Despite increased depths and frequent extreme high water, Alternative B also shows an increase in low water extremes relative to both bases and the other alternatives, with 11 events where depths dropped to more than 1.0 ft below ground, for an average of six weeks duration. This appears to be a consequence of the decompartmentalization of WCA-3 in Alternative B, which led to an increase in the frequency of both high and low extremes along the eastern side of the WCA (Indicator Regions 21 and 19), including WCA-3B (Indicator Region 16), and extending into northeast Shark River Slough (Indicator Region 11).

Central and Southern WCA-3A (Indicator Regions 14, 17 and 18)

Indicator Region 14

Alternative B performed best in this region. It is the only of the four alternatives in which extreme high water conditions (depths > 2.5 ft) did not occur; it is also the only alternative that had less extreme high water than the 2050 Base. However, only Alternative A had an inundation pattern that closely matched NSM, whereas alternatives B, C, and D, all had fewer, more prolonged inundation periods, with alternatives C and D being the wettest (11 wet periods averaging 139 weeks duration, as compared with NSM's 17 events averaging 88 weeks duration). The total percent inundation, however, was not dramatically different among the alternatives (92% in NSM, 94% in 2050 Base and Alternative B, and 95% in alternatives A, C, and D). All were much improved over the extremely long hydroperiods seen in the 1995 Base. All four alternatives showed better matches for NSM's pattern of seasonal and interannual variation in depth than the 2050 Base.

Indicator Region 17

Alternatives A and B performed well in this region. They are the only alternatives in which high water conditions did not exceed 2.5 ft for more than 1% of the overall simulation period, and they are the only alternatives that had lower frequencies of extreme high water than the 2050 Base.

Performance for inundation pattern is more complex. The target for this area is 21 inundation events averaging 74 weeks duration, which is the average of NSM values for Indicator Regions 14 and 18. Only Alternative A and the 2050 Base had inundation patterns that closely matched this target. Alternatives B, C, D all had fewer and more prolonged inundation periods, with Alternative C being the wettest (13 inundation events averaging 118 weeks duration). Alternatives B and D are nearly identical to the 1995 Base; since this Indicator Region contains grid cells around the 3A-4 gage that are presently affected by ponding along the L67-A levee, this result suggests that alternatives B and D are indeed somewhat wetter than would be ideal in this area.

Indicator Region 18

Alternative A and the 2050 Base both showed good hydrologic performance in this area. Both models exhibit an inundation pattern very similar to NSM, although both are also slightly drier than the 1995 Base. Alternatives B-D deviate greatly from target inundation patterns, with fewer than half the target number of events (ten events versus NSM's 24), and mean durations about 2.5 times as long as target values (155-156 weeks versus NSM's 59 weeks).

For high water extremes alternatives C and D perform worse than either the 1995 or 2050 bases, whereas alternatives A and B show improvement over the 1995 Base and are similar to the 2050 Base, with extreme high water only about 1% of time. For low water extremes, all the alternatives were improvements over the 1995 and 2050 bases; Alternative A, the driest overall, showed the least reduction in extreme low water, while Alternative B performed best.

Overall, Indicator Regions 14, 17 and 18

Overall, in southern and central WCA-3A, alternatives A and B performed reasonably well, and alternatives C and D performed poorly.

Only Alternative A was effective at matching target inundation patterns throughout this region, with performance very similar to the 2050 Base. Alternatives B-D were all less successful than the 2050 Base at achieving target inundation patterns. This may be a result of Component RR4, which relocated and increased the capacity of the S-140 structure, causing increased water releases directly upstream of Indicator Region 18. Combined with increased volumes of water being moved through the WCA, this produced an overall reduction in the frequency of marsh dry-outs to ground surface and a general shift toward hydroperiods that are longer than NSM. The table below illustrates this effect: not only does the total percent inundation in alternatives B-D exceed NSM values, but there is an inversion in the north-to-south gradient in hydroperiods, with the most northerly area (Indicator Region 18) having the longest percent inundation and the most southerly region (Indicator Region 14) the shortest. This is the opposite of NSM predictions for the pre-drainage gradient in hydroperiods in this region.

HYDROPERIODS FOR INDICATOR REGIONS IN SOUTH/CENTRAL WCA-3A

Indicator Region	Target	95BSR	50BSR	Alt A	Alt B	Alt C	Alt D
IR 18	89%	91%	89%	90%	97%	96%	97%
IR 17	*91%	95%	88%	88%	95%	95%	96%
IR 14	92%	99%	94%	95%	94%	95%	95%

*(Target is the average of NSM for Indicator Regions 14 and 18.)

Although Alternative A was best at matching inundation targets, Alternative B was the only alternative that effectively eliminated flooding of tree islands during high rainfall years. Hence, although Alternative A, on balance, showed the best overall performance in the central and southern WCA-3A, none of the alternatives was completely successful at meeting hydrologic performance goals for this region.

WCA-3B (Indicator Regions 15 and 16)

In this area, only Alternative A approaches target hydrologic conditions for WCA-3B. Alternative B is least favorable, primarily owing to predicted high water extremes that are comparable to those seen in WCA-2B in the 1995 Base.

WCA-3B exhibits increased depths in all four alternatives, with weekly mean depths that exceed NSM by 0.5-0.75 ft year round. Alternative B has the deepest water during the wet season, whereas Alternative D has the largest average dry season depths. With respect to inundation pattern, Alternative A was the only alternative that matched NSM, and this only in the southeast (Indicator Region 16). In all other cases, all four alternatives predicted fewer, longer duration inundation events than NSM. The poorest performer for inundation is Alternative D, which predicts only five and six inundation periods lasting an average of 319 and 262 weeks, as compared with NSM's prediction of 20 and 15 events averaging 74 and 102 weeks, for Indicator Regions 15 and 16, respectively. Generally, in western WCA-3B only the 2050 Base is a good match for NSM inundation patterns, and in southeast WCA-3B, only Alternative A and the 1995 Base approach target values.

For low water extremes, all four alternatives show improvement relative to the 2050 Base. In southeastern WCA-3B, however, all four alternatives had more extreme low water than NSM. Of the four model runs, Alternative B had the largest total amount of extreme low water (nine and 16 weeks in indicator regions 15 and 16, respectively), while alternatives A and D had the fewest weeks (0 and 11 weeks in Alternative A; one and seven weeks in Alternative D).

The most serious performance issue for WCA-3B is the high predicted frequency of extreme high water. Alternative A was the only of the four alternatives that met target values for extreme high water, with slightly fewer total high water weeks than those predicted by NSM. Relative to the 1995 Base, Alternative A has a slight increase in high water in the western WCA-3B but a decrease in eastern WCA-3B; Alternative A also performed better than the 2050 Base in both areas. Overall, only the 1995 Base and Alternative A achieved target values for high water extremes. The percents of time with extreme high water are listed in the table below for the four alternatives, the bases, and NSM. For comparison, the table also includes NSM values for indicator regions in Shark River Slough, as well as 1995 Base values for some indicator regions in areas that experience extreme depths under current C&SF Project conditions. It can be seen that alternatives B-D all substantially exceed targets for both indicator regions 15 and 16. Alternative B has the most extreme high water, equivalent to an average three month period with depths over 2.5 ft that would occur in approximately two out of every three years. When the alternatives are compared to the 1995 Base values for indicator regions representing currently deeply-ponded areas of the WCA system, it appears that impacts, even in Alternative B, would not be as extreme as those experienced to date in other areas. However, NSM values from the table suggest that the deepest areas of the pre-drainage Everglades had depths greater than 2.5 ft for up to 9% of time; hence, Alternative B, with 12-17% high water, is predicted to produce conditions outside the range for the pre-drainage system. Such depths and durations would be expected to cause significant damage to tree island vegetation communities in WCA-3B.

Percent of Time Depths Exceeded 2.5 ft in Selected Indicator Region

	Western WCA-3B	Eastern WCA-3B
	Indicator Region 15	Indicator Region 16
95BSR	1%	3%
50BSR	5%	8%
Alternatives:		
Alternative A	2%	2%
Alternative B	12%	17%
Alternative C	6%	9%
Alternative D	8%	10%
NSM Target:	2%	4%

Other NSM Values:

Mid Shark Slough	4%
NE Shark Slough	9%

Other 1995 Base Values (currently deep areas of WCA system)

IR 23:	WCA-2B	17%
IR 26:	S LNWR	30%
IR 14:	S WCA-3A	36%
IR 19:	E WCA-3A	53 %

Pennsuco Wetlands (Indicator Regions 52 and 53)

Extreme low water occurs infrequently in alternatives C and D (1-3% of time), compared with Alternative B (2-4%), Alternative A (3-6%), and especially the 1995 and 2050 bases (7-10% and 9-13% , respectively). High water extremes occur less frequently in all alternatives than under NSM, with Alternative A showing the best performance. The overall inundation pattern varies between the north and south. In northern Pennsuco (Indicator Region 52), alternatives A, B, and C all show good matches for NSM inundation patterns, whereas Indicator Region 53 comes closest to NSM in Alternative D. The NSM inundation pattern in Indicator Region 52 is similar to that for WCA-3B and southern WCA-3A, which is probably a more appropriate and achievable target for this area than is the deeper Shark

Slough-like conditions seen in NSM for Indicator Region 53. Overall, Alternative D appears to provide the best hydrologic performance for this area.

Overall Northern /Central Everglades Performance in Alternatives A-D

The four alternatives performed similarly in the final evaluations over a large area of the northern / central Everglades. Performance was fairly uniformly good in LNWR, Holey Land and Rotenberger WMAS, and northwest WCA-3A. Performance was uniformly poor in WCA-2B and eastern WCA-3A, and was uniformly problematic and uncertain in its implications for WCA-2A.

Where the four alternatives exhibited major differences in performance was in WCA-3B and in southern, central, and northeastern WCA-3A. In these areas, Alternative A provided the best overall hydrologic performance. Alternative B performed very well in southern and central WCA-3A by largely eliminating extreme high water, but this was offset by poor performance in northeastern WCA-3A, an area with important wading bird breeding habitat, and by extremely poor performance in WCA-3B, where extreme high water would be expected to damage tree islands. Alternatives C and D performed poorly in WCA-3B, and were the least favorable alternatives in central, southern and northeastern WCA-3A.

In conclusion, all of the alternatives provided improved conditions relative to the 2050 Base in parts of the northern and central Everglades, but only Alternative A came close to meeting performance targets in a majority of areas, yet it did not prevent extreme high water likely to damage tree island and rookery vegetation in WCA-3A. The only alternative that effectively avoided extreme high water in WCA-3A was Alternative B, and these benefits were offset by high water extremes in WCA-3B. Since south/central WCA-3A and WCA-3B represent the parts of the WCA 2-3 system that have been least damaged by the C&SF Project to-date, and since northeastern WCA-3A is home to currently important wading bird rookery sites, it appears that none of the four alternatives A-D can presently be regarded as likely to provide for overall restoration and sustainability of an Everglades sawgrass and ridge-and-slough ecosystem within the area encompassed by WCAs 2 and 3.

Evaluation of Alternative D13R

Subarea Evaluations

Loxahatchee NWR (Indicator Regions 26 and 27)

Loxahatchee NWR performs identically in Alternative D13R and Alternative D. The overall hydrology is similar to the 1995 Base planning target, and inundation patterns in the north are improved over the drier predictions of the 2050 Base.

Holey Land and Rotenberger WMAs (Indicator Regions 28 and 29)

Holey Land and Rotenberger WMAs perform nearly identically in Alternatives D and D13R. The regulation schedule assumed for Rotenberger WMA appears to eliminate high water extremes effectively while maintaining suitable NSM-like inundation patterns. In Holey Land, depths greater than 1.5 ft occur 7% of time, but depths greater than 1.75 ft occur only about 1% of time. In both WMAs, the frequencies and durations of extreme low water are less than those predicted by NSM; however, drought conditions still occupy 3-4% of the simulation period. Although there is uncertainty about the exact conditions needed to protect peat soils, so long as the alternative provides dry season deliveries via the STAs, it should be possible to adjust operational details so as to avoid further soil loss in these areas.

WCA-2A (Indicator Regions 24 and 25)

Overall, operational changes between Alternatives D and D13R improved performance in northern WCA-2A but reduced performance in the south. While southern WCA-2A experienced more drought conditions in Alternative D13R than in Alternative D, northern WCA-2A experienced improved inundation patterns. In the south (Indicator Region 24), extreme low water occurred 12 times averaging seven weeks in duration; this performance is inferior to the 1995 and 2050 bases and could potentially promote soil loss. In the north (Indicator Region 25), extreme low water occurred less frequently (four times averaging nine weeks duration) than in Alternative D, with frequencies that were comparable to the 2050 Base and an improvement over the 1995 Base.

Inundation patterns in northern WCA-2A were substantially improved over Alternative D. Alternative D13R had 16 wet periods averaging 93 weeks duration, in contrast to Alternative D, which had only nine periods averaging 173 weeks in length. Although neither alternative matches the NSM target of 30 events averaging 46 weeks duration, Alternative D13R comes considerably closer to the target here than does Alternative D.

It appears that water management in WCA-2A imposes trade-offs between providing improved marsh conditions in some areas but worse conditions in others. Overall, the subteam tentatively favored Alternative D13R's performance; however, a more rigorous examination of predicted conditions and effects of different operational rules will be needed in order to provide the best hydrology to those areas expected to yield the most ecological benefits. Historically, southern WCA-2A has lost most of its tree islands to past high water, while many acres of northern

WCA-2A have been overtaken by cattails. The highest quality marsh occurs in central WCA-2A in the vicinity of the 2-17 gage, and to the northwest where tree islands still persist. Inspection of stage duration curves for the 2-17 gage grid cell indicate that alternatives D and D13R are nearly identical, and that both have possibly increased high water frequencies compared to the 1995 and 2050 bases. Hence, implementation of the plan will require careful evaluation of hydrologic objectives in light of performance constraints for this area.

WCA-2B (Indicator Region 23)

WCA-2B was the only region of the northern and central Everglades to receive a “red” color evaluation for Alternative D13R. The reason for this rating is that the alternative continues to have high frequencies of both high and low water extremes. High water extremes are substantially improved over the 1995 and 2050 bases, and the number and duration of inundation events is a good match for NSM targets. However, the combination of frequent extreme low water (14 events occupying 6% of total time) and frequent extreme high water (25 events occupying 10% of total time) make it unlikely that this area will be able to function sustainably as either a shorter- or longer-hydroperiod Everglades wetland.

Northwestern WCA-3A (Indicator Regions 20 and 22)

This region performs similarly in Alternative D13R and Alternative D. Inundation patterns match NSM planning targets and high water extremes are minimal. Low water extremes occur five times for an average of three weeks duration in Indicator Region 22, and nine times for an average of five weeks in Indicator Region 20. This is a substantial improvement over the 2050 Base, and an even larger improvement relative to the 1995 Base. Conditions in this region are thus expected to maintain and promote peat soils. However, there continues to be uncertainty as to whether increased wet conditions will lead to undesirable proliferation of cattails in this area.

Northeastern WCA-3A (Indicator Region 21)

Performance of Alternative D13R is problematic, owing to predicted frequencies of extreme high and low water. The frequency of high water is increased in comparison to both the 1995 and 2050 bases, with periods of continuous depths above 2.0 ft occurring six times for an average of seven weeks in duration. During rainfall year 1994, simulated peak depths and flood durations in Alternative D13R are similar to the 1995 Base, while during rainfall year 1995, depths are deeper and of longer duration than the 1995 Base. This suggests that during high-rainfall years comparable to 1994-95, flooding can be expected to be worse than what actually occurred in this area during 1994-95. This increase in predicted high water raises concerns about potential negative effects on wading bird nesting habitat in this region. One of the most successful nesting sites for wading birds in recent years, Rescue Strand, suffered loss of perhaps as much as 75% of its willows during the 1994-95 high water period (T. Towles, GFC, pers. comm.). This rookery site is located in the same model grid cell as the 3A-3 gage, where stage hydrograph output indicates that, although depths in Alternative D13R are predicted to be lower than the 1995 Base in normal and dry years, during the wettest years (1969-70 and 1994-95) depths are predicted to equal or exceed the 1995 Base. This suggests that willow islands suitable for wading bird nesting in this area would likely be damaged, or possibly destroyed, by high water events. The problem appears to arise from the operation of STA 3/4 during peak rainfall years, when STA operational rules override marsh triggers and lead to excess discharges into this area. Changes in STA operations, additional storage, or re-routing of flood waters might alleviate or reverse this negative impact. In addition, interpretation of net impacts for wading birds is complicated by the fact that conditions to the south of the 3A-3 gage are predicted to be drier than in the 1995 Base. Hence rookery sites in eastern WCA-3A might be expected to do better under Alternative D13R than under current conditions.

An additional source of uncertainty in this area is the high predicted frequency of low water extremes. Alternative D13R performs best of all the alternatives in reducing low water extremes relative to both base cases (15 events averaging four weeks duration as compared to 21 events averaging nine weeks in the 1995 Base, and ten events averaging seven weeks in the 2050 Base). Nonetheless, the predicted frequency and duration of low water events seems large, and may not insure protection of peat soils.

Eastern WCA-3A (Indicator Region 19)

In this area, Alternative D13R has a very similar inundation pattern to Alternative D and to the 2050 Base. Although depths are much greater than NSM, they are lower than in Alternative D and much lower than the 1995 Base. High water extremes are dramatically reduced relative to Alternative D (19% in Alternative D13R compared to 27% in Alternative D). Although this performance is not as good as in the 2050 Base (with only 11% high water), and although Alternative D13R remains far from the NSM target of 0% high water, there is nonetheless enormous improvement relative to the 1995 Base prediction of 53% high water. It seems likely that this is a result of changed operations and retention of a portion of the L-67A canal, which allows more rapid removal of water from this area. Generally, eastern WCA-3A is far from its target values. However, unlike predictions for WCA-2B, extreme high water is not combined with an equivalent frequency of extreme low water. For this reason, the subteam scored the area as "yellow" rather than "red," reasoning that predicted conditions in eastern WCA-3A might support suitable habitat for snail kites and other organisms that depend on deeper water.

Central and Southern WCA-3A (Indicator Regions 14, 17 and 18)

Because performance differed distinctly among the three indicator regions in this area, results are described separately for each.

Indicator Region 14: Green

Alternative D13R performed much better than Alternative D in this area. Most notably, depths exceeded 2.5 ft only 1% of total time, compared with 6% in Alternative D. This is a substantial improvement over the 2050 Base, with 6% high water, and a dramatic improvement over the 1995 Base, which had depths greater than 2.5 ft for 36% of the total simulation. Performance in reducing high water extremes was similar but not quite as successful as Alternative B, the alternative with the best overall performance in this indicator region.

Alternative D13R, however, has more prolonged inundation than target values, averaging 139 weeks inundation duration versus 88 weeks in NSM. This pattern is slightly wetter than the longest inundation periods predicted by NSM for the northern and central Everglades, but it is still “NSM-like,” with dry-outs to ground surface averaging about once every three years. Hence, Alternative D13R was rated “green” because of its superior performance in reducing extremes of high water, while maintaining less than 1% of extreme low water. Overall, predicted hydrologic conditions in this area would be expected to promote recovery and persistence of tree island vegetation communities.

Indicator Region 17: Green

Alternative D13R performed very well in this region. Extreme high water conditions occurred only 1% of time, which is one-half the frequency in the 2050 Base and about one-fourth the frequency in the 1995 Base. This performance was similar but slightly inferior to that seen in Alternative B, the best alternative at reducing overall high water frequencies in southern and central WCA-3A. The frequency of extreme low water did not increase in Alternative D13R relative to Alternative D, and low water performance remained slightly better than the 1995 and 2050 bases.

However, Alternative D13R experienced fewer dry-outs to ground surface than its target value (14 inundation events versus a target of 21 events), with more prolonged periods of inundation (110 weeks average duration versus a target of 74 weeks). This is similar to the longer-than-NSM inundation periods seen in Indicator Regions 14 and 18.

Indicator Region 18: Yellow

In this region, Alternative D13R, like Alternative D, has a predicted inundation pattern that is much wetter than NSM. Inundation periods average 142 weeks as compared with 59 weeks for NSM, and the number of wet periods is less than half the target value (11 versus 24 events). Both the 1995 Base and the 2050 Base are better matches for NSM inundation patterns. Despite long inundation periods, however, this indicator region, like Indicator Regions 14 and 17 to the south, shows reduced occurrence of extreme high water relative to the 1995 Base, suggesting that tree island flooding will be alleviated in Alternative D13R. At the same time, low water extremes do not increase, but are actually fewer in number than in the 1995 and 2050 bases.

Overall, for central and southern WCA-3A as a whole, the principle source of uncertainty in Alternative D13R is the ecological effect of increased inundation durations, with fewer marsh dry-outs, especially within the relatively pristine area spanned by indicator regions 17 and 18. Indicator Region 17 dries out with about the same frequency as in the 1995 Base; however, Indicator Region 18 dries out less frequently. This appears to be a result of the large inflows from the S-140 structure in Alternative D13R, which passes water into and through Indicator Region 18 throughout the dry season, thus preventing the marsh from drying out in most years.

Alternative D13R is expected to be highly beneficial for tree island communities in central and southern WCA-3A. All three indicator regions show greatly reduced frequencies of extreme high water. Extreme flooding is not predicted to occur even during high rainfall years comparable to 1994-95. Furthermore, removal of the L-29 levee eliminates barriers to rapid recession of flood waters, which would be expected to help limit flooding even under more extreme rainfall conditions than those simulated in the model.

WCA-3B (Indicator Regions 15 and 16)

Alternative D13R significantly reduced the frequency of extreme high water in WCA-3B compared to Alternative D. In western WCA-3B (Indicator Region 15) Alternative D had depths that exceeded 2.5 ft for 8% of total time; this decreased to 3% of total time in Alternative D13R. In southeastern WCA-3B (Indicator Region 16), Alternative D had 10% extreme high water, and this decreased to 5% in Alternative D13R. High water performance is also better than in the 2050 Base, which had high water 5% and 8% of time in Indicator Regions 15 and 16, respectively. However, high water performance did not meet the NSM-defined targets for these areas, which predict less than 2% high water in Indicator Region 15 and less than 4% in Indicator Region 16. Only the 1995 Base and Alternative A achieved target values for high water extremes. Although Alternative D13R appears to reduce high water extremes to levels likely to prevent damage to higher hammock tree islands in WCA-3B, impacts on less-elevated tree islands still may occur.

A second source of uncertainty in Alternative D13R is the very long duration of inundation in WCA-3B relative to NSM values for the area. Western WCA-3B (Indicator Region 15) has only four inundation periods in 31 years, hence only about four dry-outs to ground level, and these inundation periods average 398 weeks in length. In eastern WCA-3B (Indicator Region 16), there are six inundation periods that average 262 weeks duration. These results differ substantially from NSM values of 20 events averaging 74 weeks, and 15 events averaging 102 weeks, in Indicator Regions 15 and 16, respectively. Both the 1995 and 2050 bases, as well as Alternative A, are better matches for NSM inundation patterns than is Alternative D13R.

Given removal of the eastern L-29 levee in alternatives B, C, D, and D13R, combined with restoration of long hydroperiods and deeper water in NE Shark Slough, it appears logically inevitable that water depths and inundation durations in WCA-3B would increase. Overall, this creates an inundation and depth pattern in WCA-3B that more closely matches NSM predictions for mid-Shark River Slough than for WCA-3B itself. Because this represents a substantial deviation from both NSM predictions of the pre-drainage hydrology of the area and current conditions in WCA-3B, extreme caution should be used in implementing changes that include such a potentially high degree of uncertainty as to the biological response to change in hydrology.

Pennsuco Wetlands (Indicator Regions 52 and 53)

Extreme low water occurs infrequently in Alternative D13R (1-2% of time); this is an improvement over alternatives A-C (3-4% low water), and a dramatic improvement relative to both 1995 and 2050 bases (7-10% and 9-13% low water, respectively). High water extremes are also rare and occur much less frequently than under NSM. The overall inundation pattern in Alternative D13R differs from NSM predictions, with Indicator Region 52 having fewer inundation events than NSM, while Indicator Region 53 has more than NSM. Inundation durations are significantly increased relative to both the 1995 and 2050 bases. Overall, Alternative D13R predicts "NSM-like" ridge and slough conditions with reduced drought frequencies. This would be expected to protect marsh soils and provide for a sustainable marsh in the area.

Summary Evaluation for Alternative D13R

Alternative D13R appears to provide the best overall performance for the WCA system. While all the alternatives perform well with respect to drought conditions that could damage peat soils, Alternative D13R provides the best overall reduction in extreme high water conditions that would flood out tree island vegetation communities, especially in southern WCA-3A and WCA-3B. Thus, Alternative D13R appears to make substantial progress toward solving the two most significant problems that have resulted from the C&SF Project in this region of the Everglades.

Two notable areas of uncertainty remain, however. One of these is the effect on wading bird populations of changes in depth patterns in northeastern WCA-3A. The more northerly parts of this area (represented by model output for the 3A-3 gage and Indicator Region 21) are predicted to become wetter, while to the south, areas east of the Miami Canal will remain deeper than NSM but will have much reduced high water frequencies compared to the 1995 Base. These conditions could be expected to improve suitable rookery sites in some areas but possibly damage others, and the distribution of suitable foraging areas will undoubtedly be changed. Although overall restoration of the Everglades watershed is expected to improve wading bird nesting habitat regionally, the timing of development of suitable breeding sites to the south of Tamiami Trail, relative to changes in current nesting sites, could have significant effects on regional wading bird populations. A more detailed analysis of anticipated effects of Alternative D13R on wading bird breeding and foraging habitat, combined with a plan for system-wide monitoring, will be important components in implementing the plan.

The second major area of uncertainty is the effect of a shift in the overall hydrologic pattern toward longer periods of inundation with fewer drying events than those predicted by NSM. The best overall match to NSM inundation patterns is Alternative A, where it appears that maintenance of the WCAs as compartments provides more control over water depths in different sections of the Everglades. With partial decompartmentalization such as that in Alternatives B and D13R, exact matches to local NSM predictions for the indicator regions in WCA-3 no longer appear to be possible, given the reduced overall extent of the Everglades watershed north of Tamiami Trail. Hence, the benefits of decompartmentalization in promoting sheetflow and reducing the frequency and duration of flooding appear to conflict with the ability of water management to match local NSM targets. In considering this apparent trade-off, the subteam concluded that the long-term sustainability of the northern and central Everglades marshes probably depended more on the avoidance of extremes of drought and flood than on exact restoration of local pre-drainage hydropatterns. Only Alternatives B and D13R manage to avoid extreme high water in southern and central WCA-3A, and only Alternative D13R accomplishes this in WCA-3B as well.

In conclusion, Alternative D13R provides inundation patterns that are “NSM-like” and that seem likely to promote a sustainable Everglades ecosystem. There nonetheless remain many uncertainties about the biological response that will occur, and these uncertainties can only be overcome by a suitable plan for adaptive management that will allow timely and informed changes in water management as deemed necessary to promoting biological restoration goals.

D.8.6 Southern Everglades

D.8.6.1 Shark River Slough

Three priority performance measures for the ecological restoration of Shark River Slough are identified in the Everglades Sloughs Conceptual Model. Those measures, in order of priority, are the duration of uninterrupted flooding, drought severity as measured by the duration of dry conditions, and the water depth during periods of flooding. Two additional performance measures that are considered in Shark River Slough analyses are the total annual flow volume and the seasonal distribution of that flow in mid Shark River Slough.

NSM45F characterized Shark River Slough as a predominantly aquatic system that was continually flooded and flowing during wet and dry seasons and during wet years and all but the most extreme dry years. NSM45F indicated that Shark River Slough would have dried only two, three and six times during the 31-year period of record in the NE, Mid and SW indicator regions, yielding uninterrupted periods of inundation that averaged 535, 401 and 226 weeks. Water depths averaged 1.8, 1.6 and 1.2 feet during periods of flooding in the three respective indicator regions. Dry conditions lasted for an average of four, three and six weeks respectively.

The 1995 Base (Revised) indicated severely over-drained conditions in Shark River Slough. The average duration of uninterrupted flooding was reduced to 74, 99 and 79 weeks in NE, Mid and SW Shark River Slough becaause the marsh dried 18, 14 and 17 times during the period of record. Water depths averaged approximately one foot during periods of flooding. Dry conditions lasted for an average of 11, 10 and 11 weeks, respectively. Total annual overland flow volume down mid Shark River Slough was 44% of that indicated by NSM45F. The seasonal distribution of that flow volume indicated a much higher proportion of the annual flow during the wet season months of July and August and a much lower proportion during the dry season months of December-February in comparison to NSM45F.

The 2050 Base (Revised) showed a slight improvement over the 1995 Base, although over-drained conditions remained in Shark River Slough. The average duration of uninterrupted flooding increased slightly to 79, 108 and 105 weeks in NE, Mid and SW Shark River Slough because the marsh dried 17, 13 and 13 times during the period of record. Water depths continued to average approximately one foot during periods of flooding. Dry conditions lasted for an average of 11, 8 and 11 weeks, respectively. Total annual overland flow volume down mid Shark River Slough increased to 52% of that indicated by NSM45F. The seasonal distribution of that flow volume indicated a higher proportion of the annual flow during the wet season months of August-October and a lower proportion during the dry season months of December-February in comparison to NSM45F.

Alternatives A-D represented improvement over the over-drained base conditions in Shark River Slough, and Alternative D demonstrated a markedly higher level of achievement of performance measures compared to Alternatives A-C. Alternative D increased the average duration of uninterrupted flooding to 263, 317 and 173 weeks in NE, Mid and SW Shark River Slough by reducing the number of drydowns to five, four and eight events respectively during the period of record. Average water depth during periods of flooding increased slightly to 1.3 feet in NE and Mid Shark River Slough. The duration of dry conditions was reduced to 6-7 weeks in all three indicator regions. Total annual overland flow volume down mid Shark River Slough was increased to 66% of that indicated by NSM45F. The seasonal distribution of that flow volume more closely resembled that of NSM45F, although a slightly higher proportion occurred during May-June, and a slightly lower proportion occurred during November-January.

Although Alternative D was substantially improved over the base conditions, it fell considerably short of the performance targets for Shark River Slough when performance was averaged over the three indicator regions. Relative to NSM45F, the duration of uninterrupted flooding in Alternative D was 53-272 weeks shorter in the three indicator regions, yielding an achievement index for the Slough as a whole of 68% compared to 25% for 1995 Base and 29% for 2050 Base. The deficiency in duration of uninterrupted flooding was due to five dry events over the period of record in Alternative D compared to two in NSM45F. The mean water depth during periods of flooding in Alternative D was deficient by 0.3-0.5 feet compared to NSM45F in the three indicator regions, yielding an achievement index for the entire Slough of 79% compared to 58% for 1995 Base and 67% for 2050 Base. Dry periods in NE and Mid Shark River Slough averaged three weeks longer in Alternative D than the 3-4 week duration indicated by NSM45F. The extended duration of dry conditions lowered the achievement index for that performance measure to 36% for the Slough as a whole. Total annual overland flow volume down mid Shark River Slough in Alternative D, which was 66% of the NSM45F flow volume, yielded an achievement index of 66% compared to 44% for 1995 Base and 52% for 2050 Base. The seasonal distribution of the annual flow volume down mid Shark River Slough, expressed as percent of the annual flow volume during each month of the year, provided a 90% match in Alternative D compared to NSM45F and yielded an achievement index of 90% compared to 76% for 1995 Base and 88% for 2050 Base.

The overall achievement index for the performance measures in Shark River Slough under Alternative D was 64% compared to 16% for 1995 Base and 26% for 2050 Base. The overall score was calculated by averaging the five performance measures over the three indicator regions with weightings of three for duration of flooding, two for duration of dry conditions, and one each for mean depth during flooding, annual overland flow volume and seasonal flow distribution. A 0.6 achievement of the hydrologic performance measures does not provide adequate assurance that the ecological values identified in the Everglades Sloughs Conceptual Model would be restored under Alternative D in Shark River Slough. Furthermore, Alternative D only partially restores hydrological and ecological connectivity of Shark River Slough in Everglades National Park to its upstream reaches in Water Conservation Area 3A due to the presence of western levee L-29. Reasonable assurance that ecological values will be restored in Shark River Slough depends on attaining an achievement index approaching 0.8 for the combined performance measures. Of particular concern is the mean duration of uninterrupted flooding as affected by the number of drydowns during the period of record. Confidence in the restoration of ecological values in Shark River Slough furthermore depends on increasing connectivity between the Park and Water Conservation Area 3, as was attempted in Alternative B.

Alternative D13R. Performance measures for the evaluation Alternative D13R in Shark River Slough were the same as those used to evaluate Alternative D, with one exception. The mean duration of dry conditions, that was used as a measure of drought severity in Shark River Slough for Alternative D, was replaced by the number of dry events during the period of record for Alternative D13R. That change was made because Alternative D13R was successful in achieving its priority goal of reducing the number of dry events in order to increase the mean duration of uninterrupted flooding. However, the dry events that were eliminated were those of shorter duration, and the longer dry events that remained represented major regional droughts when little could be done to keep Shark River Slough flooded. Thus achieving the goal of reducing the number of dry events would have penalized D13R for increasing the mean duration of dry conditions, when actually the duration of the remaining droughts in D13R was similar to that in Alternative D. Since reduction in the number of dry events became a priority for Shark River Slough in the modeling leading to Alternative D13R, it was added as a performance measure to replace mean duration of flooding.

Alternative D13R was successful in reducing the number of dry events during the period of record in order to closely approach the frequency indicated by NSM45F for Shark River Slough. The reduction in the number of dry events in NE, Mid and SW Shark River Slough from 18, 14 and 17 under 19 95BaseR and 17, 13 and 13 under 2050 Base to three, four and eight under D13R, with targets of two, three and six under NSM45F. This reduction represented an 89% achievement of the NSM45F restoration target for the Slough as a whole.

Somewhat less success was realized in increasing the prolonged mean duration of uninterrupted flooding indicated by NSM45F in Shark River Slough because of the extra one to two dry events in Alternative D13R. Alternative D13R increased the mean duration of flooding in NE, Mid and SW Shark River Slough from 74, 99 and 79 weeks under 1995 Base and 79, 108 and 105 weeks under 2050 Base to 395, 318 and 173 weeks. However, mean the mean duration of uninterrupted flooding in Alternative D13R fell short NSM45F values of 535, 401 and 226 weeks for the three indicator regions The increase in mean duration of uninterrupted flooding in NE, Mid and SW Shark River Slough achieved 76% of the NSM45F restoration target for the Slough as a whole, compared to 25% achievement under 1995 Base and 29% under 2050 Base.

Alternative D13R increased the mean water depth during periods of flooding in NE, Mid and SW Shark River Slough from 0.8, 1.0 and 0.8 feet under 1995 Base and 1.0, 1.1 and 0.9 feet under 2050 Base to 1.4, 1.2 and 1.0 feet. NSM45F values were 1.8, 1.6 and 1.2 feet for the three indicator regions. Alternative D13R mean depths during flooding achieved 79% of the NSM45F restoration target for the Slough as a whole, compared to 58% achievement under 1995 Base and 67% under 2050 Base.

Total annual overland flow volume down mid Shark River Slough in Alternative D13R was 70% of that indicated by NSM45F in comparison to 44% under 1995 Base and 52% under 2050 Base. The seasonal distribution of that flow volume, expressed as percent of the annual flow volume during each month of the year, provided a 91% match to NSM45F in Alternative D13R in comparison to a 76% match under 1995 Base and 88% under 2050 Base.

The overall achievement index for the performance measures in Shark River Slough under Alternative D13R was 82% compared to 28% under 1995 Base and 38% under 2050 Base. This score was calculated by averaging the five performance measures over the three indicator regions with weightings of three each for duration of flooding and number of dry events and weightings of one each for mean depth during flooding, annual overland flow volume and seasonal flow distribution. A 0.8 achievement of the hydrologic performance measures is considered to provide reasonable assurance that the ecological values identified in the Everglades Sloughs Conceptual Model would be restored under Alternative D13R in Shark River Slough. Confidence in the restoration of ecological values in Shark River Slough is further increased by the increased connectivity between the Slough in Everglades National Park and its upper reaches in Water Conservation Area 3 due to the removal of L-29 in Alternative D13R.

Ecological values and indicators of restoration success in Shark River Slough that are linked to the above hydrologic performance measures in the conceptual model include 1) increased nesting success and abundance of American alligators and a corresponding increase in the number of occupied alligator holes to serve as drought refugia and to increase habitat heterogeneity, 2) increased population density of aquatic fauna, 3) increased abundance of wading birds and wood storks,

4) re-establishment of coastal nesting colonies of wading birds and wood storks, 5) earlier timing of colony formation by wading birds and wood storks, 6) resumption of the return frequency of wading bird and white ibis super colonies, 7) enhanced production and community composition of periphyton, 8) accelerated accretion of peat soils, and 9) persistence and resilience of macrophyte and tree island plant communities including the cessation of sawgrass expansion into wet prairies and sloughs.

D.8.6.2 Rockland Marl Marsh

Three priority hydrologic performance measures for the ecological restoration of the Rockland Marl Marsh are identified in the Marl Prairie/Rocky Glades Conceptual Model. Those measures, in order of priority, are the duration of uninterrupted flooding, drought severity as measured by the duration of dry conditions, and the number of wet season water level reversals when the depth drops to less than 0.2 feet during a period of flooding.

NSM45F characterized the Rockland Marl Marsh as a seasonally flooded system where water levels typically dropped below the ground surface during most years, except during prolonged high rainfall periods when the marsh remained flooded for multiple years. NSM45F indicated that uninterrupted periods of inundation averaged 44 weeks. Only two wet season water level reversals occurred during 31 years. Dry conditions lasted for an average of 26 weeks.

The 1995 Base (Revised) indicated severely over-drained conditions in the Rockland Marl Marsh. The average duration of uninterrupted flooding was reduced to 12 weeks. Thirty-one wet season water level reversals occurred during 31 years. Dry conditions lasted for an average of 45 weeks.

The 2050 Base (Revised) improved conditions in the Rockland Marl Marsh, but performance still fell far short of NSM45F targets. The average duration of uninterrupted flooding was nearly doubled to 23 weeks. The number of wet season water level reversals was reduced to 18 in 31 years. The duration of dry conditions was reduced to an average of 31 weeks.

Conditions in the Rockland Marl Marsh, and Alternative D was the most successful in achieving restoration targets. The average duration of uninterrupted flooding increased to 32 weeks. The number of wet season water level reversals was reduced to three in 31 years. Dry conditions lasted for an average of 24 weeks.

Performance of Alternative D came close to achieving the restoration targets for the Rockland Marl Marsh. The mean duration of uninterrupted flooding, which was 12 weeks short of the NSM45F target, scored an achievement index of 73% compared to 27% for 1995 Base and 52% for 2050 Base. The number of wet season water level reversals exceeded NSM45F by only one and yielded an achievement index of 96%. The mean duration of dry conditions was two weeks shorter than NSM45F and thus over-achieved the target by 8%, yielding an achievement index of 92% compared to 27% for 1995 Base and 81% for 2050 Base.

The overall achievement index for the performance measures in the Rockland Marl Marsh under Alternative D was 83% compared to 22% for 1995 Base and 60% for 2050 Base. This score was calculated by averaging the three performance measures with weightings of three for duration of flooding, two for duration of dry conditions, and one for number of wet season water level reversals. A 0.8 achievement of the hydrologic performance measures is considered to provide reasonable assurance that ecological values identified in the Marl Prarie/Rocky Glades Conceptual Model would be restored under Alternative D in the Rockland Marl Marsh.

Alternative D13R. Alternative D13R prolonged the mean duration of uninterrupted flooding in the Rockland Marl Marsh from 12 weeks under 1995 Base and 23 weeks under 2050 Base to 30 weeks, in comparison to the NSM45F duration of 44 weeks. The increase in mean duration of uninterrupted flooding in the Rockland Marl Marsh achieved 68% of the NSM45F restoration target compared to 27% achievement under 1995 Base and 52% under 2050 Base.

The number of wet season water level reversals during the 31-year period of record in the Rockland Marl Marsh was reduced to four under Alternative D13R in comparison to 31 under 1995 Base, 18 under 2050 Base and two under NSM45F. The reduction in the number of reversals represented a 93% achievement of the NSM45F restoration target for the Rockland Marl Marsh.

Dry conditions in the Rockland Marl Marsh lasted for an average duration of 21 weeks under Alternative D13R in comparison to 45 weeks under 1995 Base, 31 weeks under 2050 Base and 26 weeks under NSM45F. The reduction in the mean duration of dry conditions in alternative D13R actually overshot NSM45F by 19% and achieved 81% of the NSM45F restoration target for the Rockland Marl Marsh, compared to 27% achievement under 1995 Base and 81% under 2050 Base.

The overall achievement index for the performance measures in the Rockland Marl Marsh was 76% compared to 22% achievement under 1995 Base and 60% under 2050 Base. This score was calculated by averaging the three performance measures with weightings of three for duration of flooding, two for duration of dry conditions, and one for number of wet season water level reversals. A 0.8 achievement of the hydrologic performance measures is considered to provide reasonable assurance that ecological values identified in the Marl Prairie/Rocky Glades Conceptual Model would be restored under Alternative D13R in the Rockland Marl Marsh.

Ecological values and indicators of restoration success in the Rockland Marl Marsh that are linked to the above hydrologic performance measures in the conceptual model include 1) re-colonization and population resurgence by American alligators and a subsequent increase in the number of occupied alligator holes to serve as dry season refugia for aquatic fauna and to increase habitat heterogeneity, 2) increased population density of aquatic fauna, 3) increased seasonal abundance and foraging activity of wading birds and wood storks, 4) enhanced production and community composition of periphyton, 5) accelerated accretion of marl substrate, 6) increased nesting success and population size of Cape Sable seaside sparrows, and 7) persistence and resilience of highly diverse macrophyte and tree island plant communities.

D.8.7 Florida Bay Coastal Basins

Four priority performance measures for the ecological restoration of the Florida Bay coastal basins are identified in the Florida Bay Mangrove Estuarine Transition Conceptual Model. All performance measures are based on relationships between mean monthly salinity in five coastal basins, from Joe Bay to North River Mouth, to water stage at the P33 gage in mid Shark River Slough.

One measure is the number of months during the period of record when stages equal or exceed 6.3 feet msl at P33. Stages above 6.3 at P33 correspond to a reduced frequency of undesirable high salinity events in the coastal basins. A second measure is the number of months during the period of record when stages equal or exceed 7.3 feet msl at the P33 gage. Stages above 7.3 at P33 correspond to an increased frequency of desirable low salinity events in the coastal basins. The reduced frequency of undesirable high salinity events when the P33 stage reaches 6.3 is given a higher priority than the increased frequency of desirable low salinity events when the P33 stage reaches 7.3.

A third measure is the cumulative salinity difference (ppt) from the undesirable high salinity levels that were identified for each basin. Cumulative differences from high salinity levels are summed during the dry/wet season transition months of March-June. A fourth measure is the cumulative salinity difference (ppt) from desirable low salinity levels that were identified for each basin. Cumulative differences from low salinity levels are summed during the wet/dry season months of August-October. These differences are summed over the five coastal basins and over the 31-year period of record. Differences above the specified high or low salinity levels are given a positive value, and differences below the specified high or low salinity levels are given a negative value. The performance targets are to reduce cumulative salinity differences to values that do not exceed the cumulative differences produced by NSM45F.

NSM45F characterized the Florida Bay coastal basins as estuarine environments that experienced low to moderate salinity well below seawater concentrations the majority of the time. The coastal basins would have avoided high salinity events, (>15 to >35 ppt depending on the basin) during 258 months of the 372-month period of record when P33 stages rose to 6.3. Low salinity events (<5 to <25 ppt, depending on the basin) would have occurred during 30 months of the period of record when P33 stages rose to 7.3. The cumulative salinity difference from concentrations that marked high salinity events during March-June totaled 440 over the five basins and 31 years, while the cumulative salinity difference from concentrations that marked low salinity events during August-October totaled 525.

The 1995 Base (Revised) indicated a prevalence of high salinity conditions and a paucity of low salinity events that shifted the the estuarine environments of the coastal basins to more marine conditions. The coastal basins experienced high salinity events during two-thirds of the period of record, when P33 stages fell below 6.3 for 247 out of 372 months. Low salinity events occurred only during seven of the 372 months. The 31 year cumulative salinity difference from concentrations that marked high salinity events during March-June totaled 2755, while the cumulative difference from concentrations that marked low salinity events during August-October totaled 1765.

The 2050 Base (Revised) showed only slight improvement over 1995 Base in salinity regimes in the coastal basins. High salinity events were less frequent and occurred during 195 out of 372 months, but low salinity events were also less frequent and only occurred during two out of 372 months. Cumulative salinity differences from concentrations that marked high and low salinity events during the periods of March-June and August to October were slightly reduced to 2515 and 1545, respectively.

Alternatives A-D all substantially improved salinity regimes in the coastal basins, and each alternative was approximately equally effective in overall performance. Alternative D decreased the number of high salinity events to 164 months and avoided high salinity events during 208 months of the 372-month period of record. Alternative D increased the number of low salinity events to 25 during the period of record. The 31 year cumulative salinity difference from concentrations that marked high salinity events during March-June totaled 735, while the cumulative salinity difference from concentrations that marked low salinity events during August-October totaled 1155.

Performance of Alternative D approached restoration targets for the Florida Bay coastal basins for three of the four performance measures. The number of months when P33 stages rose to 6.3 was 81% of NSM45F compared to 48% for 1995 Base and 69% for 2050 Base. The months when P33 stages rose to 7.3 was 83% of NSM45F compared to 23% for 1995 Base and 7% for 2050 Base. The cumulative salinity difference from concentrations that marked high salinity events during March-June scored an achievement index of 87%, but the cumulative salinity difference from concentrations that marked low salinity events during August-October scored an achievement index of only 49%, both relative to an NSM45F score of 100%.

The overall achievement index for the performance measures in the Florida Bay coastal basins under Alternative D was 78% compared to 20% for 1995 Base and 30% for 2050 Base. A similar achievement index, rounded off to 0.8, was also attained for Alternatives A-C. These scores were calculated from the four performance measures with weightings of two for the number of months when stages equaled or exceeded 6.3 at P33, one for the number of months when stages equaled or exceeded 7.3 at P33, two for cumulative salinity differences from undesirable high levels during March-June, and one for cumulative salinity differences from desirable low levels during August-October. A 0.8 achievement of the hydrology/salinity performance measures is considered to provide reasonable assurance that the ecological values identified in the Florida Bay Mangrove Estuarine Transition Conceptual Model would be restored under Alternative D in the Florida Bay coastal basins.

Alternative D13R. Alternative D13R was successful in avoiding high salinity events (>15 to >35 ppt, depending on the basin) in the Florida Bay coastal basins during 228 months of the 372-month period of record when P33 stages rose to 6.3 feet msl. In comparison, high salinity events were avoided during 258 months under NSM45F, 125 months under 1995 Base, and 177 months under 2050 Base. The reduction in the number of high salinity events achieved 88% of the NSM45F restoration target under Alternative D13R compared to 48% achievement under 1995 Base and 69% under 2050 Base.

Alternative D13R was successful in attaining low salinity events (<5 to <15 ppt, depending on the basin) in the Florida Bay coastal basins during 18 months of the period of record when P33 stages rose to 7.3 feet msl. Low salinity events were attained during 30 months under NSM45F, seven months under 1995 Base, and only two months under 2050 Base. The increase in the number of low salinity events achieved 60% of the NSM45F restoration target under Alternative D13R compared to 23% achievement under 1995 Base and 7% under 2050 Base.

The 31 year cumulative salinity difference from concentrations that marked high salinity events during March-June decreased from 2755 under 1995 Base and 2515 under 2050 Base to 660 under Alternative D13R. The NSM45F target was 440. The reduction in the March-June cumulative salinity difference represented a 91% achievement of the NSM45F restoration target for the Florida Bay coastal basins.

The 31 year cumulative salinity difference from concentrations that marked low salinity events during August-October decreased from 1765 under 1995 Base and 1545 under 2050 Base to 1025 under Alternative D13R. The NSM45F target was 525. The reduction in the August-October cumulative difference represented a 60% achievement on the NSM45F restoration target for the Florida Bay coastal basins.

The overall achievement index for the performance measures in the Florida Bay coastal basins under Alternative D13R was 80% compared to 20% for 1995 Base and 50% for 2050 Base. These scores were calculated from the four performance measures with weightings of two for the number of months when stages equaled or exceeded 6.3 at P33, one for the number of months when stages equaled or exceeded 7.3 at P33, two for cumulative salinity differences from undesirable high levels during March-June, and one for cumulative salinity differences from desirable low levels during August-October. A 0.8 achievement of the hydrology/salinity performance measures is considered to provide reasonable assurance that the ecological values identified in the Florida Bay Mangrove Estuarine Transition Conceptual Model would be restored under Alternative D13R in the Florida Bay coastal basins.

Ecological values and indicators of restoration success in the Florida Bay mangrove estuary and coastal basins that are linked to the above hydrology/salinity performance measures in the conceptual model include 1) increased production of low-salinity mangrove fish and invertebrates, 2) re-establishment of coastal nesting colonies of wading birds and wood storks and eastern Florida Bay colonies of roseate spoonbill, 3) earlier timing of coastal colony formation by wading birds and wood storks, 4) resumption of the return frequency of wading bird and white ibis super colonies, 5) increased growth and survival of juvenile American crocodiles, 6) increased cover of low-to-moderate salinity aquatic macrophyte communities in coastal lakes and basins, 7) return of seasonal waterfowl aggregations to coastal lakes and basins, 8) enhanced nursery ground value for sport fishes and pink shrimp in coastal basins, and 9) persistence and resilience of the mangrove, salt marsh and tidal creek vegetation mosaic.

D.8.8 Model Lands / C-111 Area

Description of Performance Measures:

The Model Lands Alternatives Evaluation Matrix consists of five or six performance indices, which are applied to each of the four indicator regions in the Model Lands area: 4, 5, 6, and 47. Indicator Regions 4 and 47 are located immediately west of US 1 and in proximity to the C-111 Canal. Indicator Regions 5 and 6 are located east of US 1. Initial scores for performance indices 1 through 4 were obtained from stage duration curves. Initial scores for performance indices 5 and 6 were obtained from the data tables supporting the inundation pattern curves. For performance indices 1 through 4, stage durations are examined in relation to specified high and low water depth thresholds, which were based on land elevation and vegetation cover and differ for each indicator region, as follows:

Indicator Region	Name	High (ft)	Low (ft)
4	C111 Perrine Marl Marsh	2	0.5
5	Model Lands South	2	0.5
6	Model Lands North	1.75	0.25
47	C111 North	1.75	0.001

Following is a brief description of each performance index.

High water index: The proportion of time that water levels are below the high water threshold which has been specified for the indicator region (calculated as [1 - proportion of time water levels are above a specified level]). The target is 1.00, however proportions down to 0.90 are acceptable to allow for interannual variation. This index quantifies the period of time that water levels are so high that they may stress the vegetation communities naturally characteristic of these areas.
Low water index: The proportion of time that water levels are above the specified low water threshold. The target is 1.00. This criterion seeks to minimize the period of time that water levels are below a specified low water level.

Extreme low water index: The proportion of time that water levels less than 1 ft below the specified low water threshold. Calculated as (1 – proportion of time water levels are >1 ft below the specified low-water threshold). Target is 1.00. Values near 1 indicate that dry season levels are above the extreme low water level almost all of the time. Values closer to 0 indicate that dry season water levels typically fall at least another foot below the specified low water level.

Relative dry period slope index: Relative measure of the steepness of the slope of the stage duration curve during dry periods. Calculated as (1-(value for low water index divided by value for extreme low water index)). The index can vary from almost 0 (very steep slope; water levels drop dramatically during dry periods) to approximately 1.0 (slope shallow; water levels relatively stable throughout the dry season). Values closer to one are preferred.

Wet Season Inundation Pattern Index: Proportional measure of how many times during the 31-yr simulation that water levels drop below surface elevation during the July-October portion of the wet season. Calculated as (Value for Alternative – Value for Best Alternative) divided by (Value for Worst Alternative – Value for Best Alternative). The best alternative received a score of 1.0 and the worst received a score of 0.0. This criterion gives a relative ranking for how many times the aquatic habitat is disrupted by drydowns during the core months of the wet season. The months June and November were omitted from the analysis to allow for variation early and late in the season.

Dry Season Inundation Pattern Index: Proportional measure of how many times during the 31-yr simulation that water levels rose above surface elevation during the January – May portion of the dry season. (The months November and June were omitted to allow for variations in rainfall early and late in the season.) Calculated as [(Value for Alternative – Value for Best Alternative) divided by (Value for Worst Alternative – Value for Best Alternative)]. The best alternative received a score of 1.0 and the worst received a score of 0.0. This criterion was an attempt to measure the relative effect of dry season flooding on wading bird feeding during the nesting season. Continuous drying, once the dry season commences, is important to wading bird feeding and nesting. Additionally, the region is adjacent to an active nesting population of Cape Sable Seaside Sparrows, who breed in short hydroperiod wetlands during the dry season, provided the ground is not flooded. Since there is some possibility for range expansion into the region if the area is suitable, this index was designed to look at tradeoffs between providing wading bird feeding habitat and sparrow breeding habitat. This index was calculated, but the results were complicated by the already uncharacteristically dry condition of the region, making it difficult to interpret the results. Raw scores for this index are presented, but were not used to calculate the final score.

Late Wet Season Inundation Index: Proportional measure of how many times during the 31-yr simulation that autumn periods of inundation ended during the months of November and December. This index was applied only to Indicator Region 5 (Model Lands South), which includes habitat critical for Roseate Spoonbill feeding. A good year for wading bird feeding would be characterized by standing water in this indicator region well into January. Premature drydowns in the early dry season in this region may severely reduce available food to support Roseate Spoonbill nesting. Calculated as (Value for Alternative – Value for Best Alternative) divided by (Value for Worst Alternative – Value for Best Alternative). The best alternative received a score of 1.0 and the worst received a score of 0.0.

The individual scores were weighted evenly and averaged for each alternative within each indicator region to get comparative scores. Table Model Lands - 1 provides the individual performance index scores, average scores, and ranking of alternatives for each indicator region, followed by an overall evaluation for the Model Lands area. Individual scores for each indicator region are shown separately in Table Model Lands - 1 because of strong differences in results among the regions. Table Model Lands - 2 shows all the scores that were calculated, including some not used in the ranking.

Interpretation:

Alternatives A through D

Overall, alternatives that added water to this region yielded higher scores than alternatives that did not. Alternatives B, C, and D consistently scored higher than the base conditions or Alternative A. There were differences among the indicator regions, however, in which alternative produced the best results. Alternative B had the highest score for Indicator Regions 4 and 47 (areas west of US1), while alternatives C and D were essentially indistinguishable for Indicator Regions 5 and 6 (areas east of US1). Alternative B provided additional water to Indicator Region 4 and Indicator Region 47 via the C-111N canal. Alternatives C and D extended the C-111N to Indicator Region 5, which spread the additional water over a larger area and reduced the water remaining in Indicator Region 4 and Indicator Region 47. Alternatives C and D were the configurations resulting in the greatest benefits to the region as a whole and are preferred to Alternative B for that region. A design that benefits the entire region is preferred to one that benefits only a part of it. Furthermore, should an additional source of high quality water be identified in the future, alternatives C or D will provide the infrastructure necessary to distribute this water throughout the Model Lands area. Regional managers are already attempting to reduce artificial hydrological barriers between these indicator regions and manage the entire area as a connected system. Selecting an alternative that benefits the entire area is consistent with their management objectives.

The alternatives that perform the best in this region still are far from meeting targets relative to low water. The objective was to maintain water levels above the stated low water threshold all the time. These targets were based on land elevations and general requirements for historic vegetation communities. Although alternatives C and D, compared with base conditions, improved conditions in the region as a whole, these alternatives still did not reach stated targets. Water levels were below the low water thresholds more than half the time in all four indicator regions.

Alternative D - D13R

The configuration and operation changes from Alternative D to D13R made no difference to hydrologic conditions in the Model Lands-C111 Area. There were no changes in any of the performance indices from D to D13R. According to the performance indices, the water needs of the Model Lands-C111 Area still are not met, although conditions will be improved if either Alternative D or D13R are implemented.

Concerns

Many concerns should be addressed in the detailed design phase. Additional water is needed for the Model Lands-C111 Area. Furthermore, the quality and quantity of some of the water provided to the South Miami-Dade area in Alternative D13R must be confirmed. Some of the benefits in Indicator Region 5 and Indicator Region 6 may have originated from the regional use of advanced treatment wastewater to maintain canal stages in South Miami-Dade, but this option may prove too costly or too impractical to implement.

The benefits of having higher water levels in the Model Lands-C111 Area are clear. Alternative sources of water should, therefore, be identified and investigated as part of the design process.

The specific location and design for the water delivery system need to be carefully considered to minimize impacts to existing high quality wetlands and avoid disrupting the natural system with excessive infrastructure. To maximize benefits, an effort should be made to improve the design to ensure that the best configuration of components has been achieved.

D.8.9 Big Cypress

Area/Subregion/Indicator Regions

Different portions of the Big Cypress subregion are used in the different matrix equations.

Performance Measures
1. Mean NSM Hydroperiod Matches for North Big Cypress National Preserve for the 31 year simulation
2. Mean NSM Hydroperiod Matches for South Big Cypress National Preserve for the 31 year simulation
3. Normalized Weekly Stage Duration Curves for Indicator Regions 13, 31, 36-40, 45, and 42-43
4. Average Annual Overland Flows toward Gulf of Mexico from Big Cypress National Preserve for the 31 year simulation
5. Inundation Duration Summary for Indicator Regions: Average Flood Duration

Scoring Explanation

All of the scores are relative to NSM conditions in the Big Cypress.

A = percent of North Big Cypress National Preserve that matches NSM (PM #1)

This provides a spatial measure of one of the more impacted portions of the Big Cypress that lies along its northern border. Impacts are due primarily to agricultural development and its associated canals upstream (north) of this area. In addition, there may be some model boundary problems in this area, possibly related to the fact that the area to the north is included in the Natural System Model, but not the South Florida Water Management Model.

B = percent of South Big Cypress National Preserve that matches NSM (PM #2)

This provides a spatial measure of the relatively unimpacted portion of the Big Cypress. This area is dominated by rainfall inputs, and as a result, exhibits few effects of hydrologic alterations beyond its boundaries. Hydrologic effects of the Restudy alternatives occur primarily along the Big Cypress boundary with the Everglades.

C (for individual Indicator Regions) = 1 - {absolute number}
[(percent of time flooded for NSM) - (percent of time flooded for Base or Alternative)] /100} (PM #3)

This provides a measure of deviation from NSM hydroperiod for an indicator region. This deviation is almost always a reduction in hydroperiod. The selected indicator regions are all in the eastern portion of the Big Cypress near its border with the Everglades, since there is little effect of any of the alternatives on the western portion of the Big Cypress. Initially all of the indicator regions were evaluated separately (Table Big Cypress - 1).

Equations were developed to combine some indicator regions in a simple additive form because of different influences in different areas (Table Big Cypress - 2). Indicator Regions 31, 36-40, and 45 were combined since they are all probably influenced by flows in the vicinity of South L-28 (South Big Cypress). Indicator Regions 42 and 43 were combined since they are both in the area affected by the L-28 Interceptor and the Western Feeder Canal (North Big Cypress). Indicator Region 13 was not combined with any other Indicator Regions (Southeast Big Cypress).

D_n(for individual Indicator Regions) = 1 – absolute number [(maximum deviation from NSM hydrograph) / (maximum range of NSM water level fluctuation)] (PM #3)

This provides a measure how much water levels have been altered from NSM conditions as a function of the NSM range of fluctuation for an indicator region. A certain degree of deviation in an area with a large natural fluctuation would be less significant than in an area with a small natural fluctuation. Typically, the greatest deviation occurs when the water table is declining through the first foot or two below the ground surface, it is smallest at its lowest point on the hydrograph, and it is relatively small when the water table is above ground. The selected indicator regions are all in the eastern portion of the Big Cypress near its border with the Everglades, since there is little effect of any of the alternatives on the western portion of the Big Cypress. Initially all of the indicator regions were evaluated separately (Table Big Cypress - 1).

Equations were developed to combine some indicator regions in a simple additive form because of different influences in different areas (Table Big Cypress - 2). Indicator Regions 31, 36-40, and 45 were combined since they are all probably influenced by flows in the vicinity of South L-28 (South Big Cypress). Indicator Regions 42 and 43 were combined since they are both in the area affected by the L-28 Interceptor and the Western Feeder Canal (North Big Cypress). Indicator Region 13 was not combined with any other Indicator Regions (Southeast Big Cypress).

G = 1 – absolute number [(deviation of average flood duration from NSM average flood duration) / (NSM average flood duration)] (PM #5)

This provides a measure of deviation from NSM for average duration of individual flooding events for an indicator region. This deviation is usually a reduction in the duration of inundation. The selected Indicator Regions are all in the eastern portion of the Big Cypress near its border with the Everglades, since there is little effect of any of the alternatives on the western portion of the Big Cypress. Initially all of the indicator regions were evaluated separately (Table Big Cypress - 1).

Equations were developed to combine some indicator regions in a simple additive form because of different influences in different areas (Table Big Cypress - 2). Indicator Regions 31, 36-40, and 45 were combined since they are all probably influenced by flows in the vicinity of South L-28 (South Big Cypress). Indicator Regions 42 and 43 were combined since they are both in the area affected by the L-28 Interceptor and the Western Feeder Canal (North Big Cypress). Indicator Region 13 was not combined with any other Indicator Regions (Southeast Big Cypress).

E_w = 1 – absolute number [(deviation of wet season flows from NSM flows) / (NSM wet season flows)] (PM #4)

E_d = 1 – absolute number [(deviation of dry season flows from NSM flows) / (NSM dry season flows)] (PM #4)

Total flows during the wet and dry season provide another way of expressing hydrologic conditions and how they change in response to proposed alternatives in particular portions of the Big Cypress. The flow cross-sections evaluated included the Eastern Big Cypress and Lostman's. Initially the flow cross-sections were evaluated separately by wet and dry season (Table Big Cypress - 1).

The subteam has developed simple additive equations for each flow cross-section to combine the wet and dry season information (Table Big Cypress - 2).

Summary Equations

The subteam subsequently developed summary equations for major geographic regions of the Big Cypress that were distinct in terms of their response to the various Restudy alternatives (Table Big Cypress - 2). These major areas were: **North Big Cypress**, which was only affected by Alternatives C and D where the L-28 Interceptor canal and levee system were modified; **South Big Cypress**, which was affected primarily by alterations to the south end of the L-28 canal and levee and in the adjacent Water Conservation Area 3A; and **Southeast Big Cypress**, which being on the border between the Everglades and southeast portion of the Big Cypress Swamp, is affected by the numerous alterations to the Everglades.

For each of these geographic areas, a simple additive equation was developed to combine variables C_n, D_n and G_n for the same indicator region(s) to summarize information on deviations in hydroperiod, water depth, and average flood event duration in these areas. In North Big Cypress, variable A was included in this simple additive equation. In South Big Cypress, variable B and variable E were included for flows across the Eastern Big Cypress along Tamiami Trail. In Southeast Big Cypress, variable E was included for flows across the Lostman's cross-section south of Tamiami Trail.

A single equation was also developed that combined the three Big Cypress regions.

Discussion

Scores were developed separately for each variable in each indicator region and for each cross-section or boundary (Table Big Cypress - 1). They were then combined in a stepwise fashion, as described above, so that the AET would be able to comment on what is gained and lost as each performance measure was combined with others. Originally two sets were developed (with or without flows) of the three summarizing equations, with the goal of reducing all of the variables to three scores, one for the North Big Cypress, one for the South Big Cypress, and one for the southeastern Big Cypress. Ultimately two whole Big Cypress equations were produced, again depending on whether flow parameters are used or not in the equations.

As a result of discussions at the late May AET meetings, it was decided to focus on using the information contained in the three geographically-separate equations that included the flow cross-section information (Table Big Cypress - 2). Each of these three summary rows of the matrix provided distinctive information relevant to understanding influences that each of the Alternatives had on the Big Cypress.

All of the effects on the North Big Cypress occurred in alternatives C and D, and were retained in D13 and D13R. The effects resulted from filling the L-28 Interceptor Canal and removing its western levee, creating openings for water to move south along the Western Feeder Canal, and replacing S-190 with a pump station to maintain upstream drainage. This scenario also required some sort of water treatment capability to assure that all water moving south and southwest from the upstream canal system would provide only clean water. These components converted an area about two cells wide for most of the length of the L-28 Interceptor along its western side to approximately NSM conditions. Because the locations of the restored cells and the indicator regions available in the vicinity were not the same, the low matrix scores did not adequately reflect the high degree of restoration that actually occurred in portions of this area from the implementation of these components.

In the South Big Cypress, the most significant changes occurred in Alternative D, with the removal of the L-28 Tieback Levee. With this structure removed, hydrologic conditions showed almost complete restoration to NSM conditions, including restored hydroperiods and increased flows across the eastern portion of the Big Cypress. The model results for D13 and D13R were almost identical to one another, and both showed generally small but distinct increased deviations from NSM as compared to Alternative D. The matrix values for D13 were almost identical to the 1995 Base conditions in this area, but were higher than for the 2050 Base. When looking at the hydrologic responses to these alternatives for individual performance measures and indicator regions, the geographic area where the deviations were greatest was in the vicinity and downstream of the jetport. When we first noticed this, we thought it might be a function of how the jetport was configured in the model. However, the jetport and its associated fill are not included in the SFWMM, even though it is large enough that it probably could be included on a 2X2 mile grid scale. We next looked at topography in the area, which turned out to be slightly lower in some grid cells to the east of the south L-28 in the SFWMM than in the NSM. This could probably explain the slightly greater differences from NSM in this area compared to Alternative D, where south L-28 was still pesent and would limit the southest flow of water cominf through the gap creeated by removal of the L-28 Tieback levees. In Alternative D13R, this water could move more easily to the south east since the south L-28 and L-29 were gone.

In the southeastern Big Cypress along its border with the Everglades and below Tamiami Trail, the most significant changes occurred in Alternative B, when the L-28 and L-29 levees and canals were removed. According to the model, there were larger areas showing reduced hydroperiods and the reductions in hydroperiods and flows were greater than in Alternatives A, C, or D, all of which were close to NSM condition. In Alternative C, the L-28 and only the western portion of L-29 were restored, which was sufficient to return conditions in this area close to NSM. The removal of the L-28 Tieback in Alternative D did not seem to affect this portion of the Big Cypress. Alternatives D13 and D13R produced generally small and variable responses among the various performance measures, resulting in an overall minor difference in the summary matrix value for this portion of the Big Cypress.

Summary

The combination of components in Alternative D produced the greatest benefits in terms of restoring the largest amount of area in the Big Cypress to approximately NSM conditions. It also seems that several of the most beneficial components could be implemented in any of the alternatives, since they operate pretty much independently from the rest of the Everglades ecosystem. This would be the situation for the L-28 Interceptor and L-28 Tieback components. Changes to the L-28 South and L-29 have more extensive and complex interactions with other parts of the Everglades.

In using the colors and grades to differentiate restoration success as indicated by the various performance measures for each the bases and alternatives (A-D, D13, D13R), matrix value ranges of 91-100 (green, grade A), 81-90 (yellow, grade B), and <81 (red, grade C) were used. These ranges generally seemed to do a reasonably good job of sorting restoration gains and losses for the Big Cypress region that were associated with each of the alternatives. The only portion of the region where these results could be misinterpreted is the North Big Cypress. The portion of this area influenced by the L-28 Interceptor system should be included in the green grade A category in Alternatives C, D, D13, and D13R. The portion further west still shows severe hydrologic impacts, even in these latter alternatives. However, based on a helicopter overflight of the area to assess its condition and understanding of how the models are operating in this area, it is very likely that these impacts are merely the result of modeling problems, and in reality are much less severe than suggested by the SFWMM.

D.8.10 Caloosahatchee Estuary

Variables and Performance Measures. The following variables were developed using existing performance measures for Caloosahatchee Estuary. The variables / performance measures have targets based on flow which would support optimum hydrologic conditions conducive of optimum quality habitat for fish, wildlife, and other aquatic resources. The targets are based on optimization model outputs, natural variation that would occur during the period 1965-1995, and desirable salinity conditions for existing and potential aquatic resources within the Caloosahatchee Estuary. These are not all of the existing performance measures for the Caloosahatchee Estuary but are a subset selected by the subteam to be used to evaluate Restudy Plans. There are additional performance measures posted on the Restudy webpage that provide additional detailed information. These additional performance measures were determined to be a lower level priority to be used in the present Restudy evaluation and may not be included in Restudy AET presentations/evaluations.

Variables, SIVs. The four variables / performance measures for the Caloosahatchee Estuary are as follows:
SI**V*min*** = # months mean monthly flow< 300 cfs from C-43 & LOK during dry season (Nov – May)

SIV*max2800* = # months mean monthly flow > 2,800 cfs
SIV*max4500* = # months mean monthly flows were > 4,500 cfs
SIV*max7800* = # days LOK Reg. Discharges>7,800 cfs.

SIV*min*. This variable is based on the number of months with mean monthly flow< 300 cfs. This variable is based on the number of times the minimum mean monthly flows from the lake and watershed fall below 300 cfs at S-79 for the 1965-1995 period. The alternative with the least number of times flows fall below 300 cfs, as measured at S-79, will be considered better for protecting estuarine aquatic biota. The target number of months not to be exceeded is 60 for the 1965-1995 period.

Principal Objective: Maintain sufficient minimum mean monthly flows from the lake to augment basin runoff, when necessary, in order to maintain favorable salinities and water quality within the estuary.

Rationale: Insufficient fresh water discharges, contribute to poor estuarine water quality including inadequate fresh water to maintain desirable salinity envelopes. These events have had direct effects on estuarine seagrasses, fish and invertebrates, including critical indicator species eg. Vallisneria, by enabling the estuary to become too saline

Outputs for SIV*min*: As stated above, the ROGEM indices are ordinal rather than cardinal numbers. The total allowable number of monthly violations is based on the natural variation of hydrologic conditions during the period 1965 to 1995. The results of hydrologic modeling indicate that the optimum senario would have no more than 60 months of mean monthly flows of <300 cfs. The Caloosahatchee data for the alternatives is taken from the performance measures bar graphs and tables titled "Number of times Salinity Envelope Criteria were NOT met for the Caloosahatchee Estuary."

The ROGEM output for this variable is calculated using the formula:

$$1 - \frac{\text{observed \# of months - target \# of months}}{\text{range (observed max \# of months for all Alts - target)}}$$

Note: The output is set at 1.0 (i.e. does not exceed 1.0) which indicates optimum conditions.

Results for SIV*min* are presented in Table Caloosahatchee Estuary - 1.

SIV*max2800*. This variable is based on the number of times mean monthly flow exceeds 2,800 cfs as measured at S-79 from the lake and the watershed for the 1965-1995 period. The maximum number of months (target) allowing for natural variation is 22 for the 1965-1995 period of record. The alternative with the least number of times flows exceed 2,800 cfs as measured at S-79, at any time of year, will be considered better for maintaining desirable salinity and water quality within the estuary.

Principal Objective: Achieve an overall reduction in high volume discharge events to the estuary, and improve estuarine water quality. This will benefit estuarine vegetation, invertebrates, and fish communities.

Rationale: High volume discharges to the estuary contribute to poor estuarine water quality including increased turbidity, color and violation of favorable salinity envelopes. High flow events have direct effects on estuarine seagrasses by reducing light penetration necessary for photosynthesis, destroying fish and invertebrate habitat, and contributing to unfavorable salinities for aquatic vegetation, fish and invertebrates, including critical indicator species e.g., the American oyster, turtle grass, and Vallisneria.

Outputs for SIV*max2800:* As stated above, the ROGEM scores are ordinal rather than cardinal numbers. The total allowable number of monthly violations is based on the natural variation of hydrologic conditions during the period 1965 to 1995. The results of hydrologic modeling of this period indicate that the optimum scenario would have no more than 22 months of mean monthly flows of >2,800 cfs. The Caloosahatchee Estuary data for the alternatives is presented in the performance measures bar graphs and tables titled "Number of times Salinity Envelope Criteria were NOT met for the Caloosahatchee Estuary."

The ROGEM output for this variable is calculated using the formula:

$$1 - \frac{\text{observed \# of months - target \# of months}}{\text{range (observed max \# of months for all Alts - target)}}$$

Note: The maximum output is set at 1.0 (i.e. does not exceed 1.0) which indicates optimum conditions.

Results for SIV*max2800* are presented in Table Caloosahatchee Estuary - 1.

SIV*max4500*. This variable is based on the number of times mean monthly flows exceed 4,500 cfs at S-79 for the 1965-1995 period of record. The acceptable number of months (target) allowing for natural variation is 6 for the 1965-1995 period. The alternative with the least number of months that discharges exceed 4,500 cfs as measured at S-79, will be considered better for protecting estuarine resources, including those downstream in the San Carlos Bay region.

Principal Objective: Reduce the occurrence of extreme discharge events and improve water quality in the lower estuary, including San Carlos Bay, in order to protect estuarine resources.

Rationale: Mean monthly flows above 4,500 cfs results in freshwater conditions throughout the entire estuary causing impacts to estuarine biota. This volume of flow also begins to reduce water quality and adversely impact biota in San Carlos Bay.

Outputs for SIV*max4500:* The ROGEM scores are ordinal numbers. The total allowable number of monthly violations, based on natural variation of hydrologic conditions, and hydrologic modeling of this period indicate that the optimum condition is to have no more than 6 months of mean monthly flows of >4,500 cfs. The Caloosahatchee Estuary data for the alternatives is presented in the performance measures bar graphs and tables titled "Number of times Salinity Envelope Criteria were NOT met for the Caloosahatchee Estuary."

The ROGEM output for this variable is calculated using the formula:

$$1 - \frac{\text{observed \# of months - target \# of months}}{\text{range (observed max \# of months for all Alts - target)}}$$

Note: Output is set at 1.0 (i.e. does not exceed 1.0) which indicates optimum conditions

Results for SIV*max4500* are presented in Table Caloosahatchee Estuary - 1.

SIV*max7800*. This variable is based on the number of days of Zone A discharge from the lake for each alternative for the period 1965-1995. The target is zero (0) violations. This variable considers the number of days of Zone A discharge from the lake (7,800 cfs per day at S-79, not S-77) for each alternative for the 1965-1995 period of record. The alternatives with the least number of days of Zone A release according to output from the SFWMM will be considered better for protecting the integrity of the estuarine environment.

Principal Objective: Reduce the occurrence of extreme discharge events from the lake to the estuary, and improve estuarine water quality with a view to protecting estuarine aquatic biota.

Rationale: Zone A discharges have rapid and serious effects on estuarine seagrasses in the Caloosahatchee River Estuary and San Carlos Bay by reducing light penetration necessary for photosynthesis. Zone A discharges destroy fish and invertebrate habitat, and contribute to unfavorable salinities for estuarine biota, including critical indicator species e.g., the American oyster, Vallisneria, and other vegetation. The longer Zone A discharges persist, the greater the damage to the various ecosystems, and the further the damage extends.

Outputs for SIV*max7800*: No Zone A discharges of this magnitude are desirable. Furthermore, the results of hydrologic modeling of the period 1965-1995 indicate that no daily flows of >7,800 cfs would have occurred during this period. The Caloosahatchee Estuary data for the alternatives is presented in the performance measures bar graphs and tables titled “Number of times Salinity Envelope Criteria were NOT met for the Caloosahachee Estuary.”

The ROGEM output for this variable is calculated using the formula:

$$1 - \frac{\text{observed \# of days}}{\text{range (observed max \# days for all alts)}}$$

Note: Output is set at 1.0 (i.e. does not exceed 1.0) which indicates maximum conditions.

Results for SIV*max7800* are presented in Table Caloosahatchee Estuary - 1.

ROGEM equation and final scores for Caloosahatchee Estuary

The variables can be prioritized from lowest to highest, according to the following: SIVmin is the lowest priority variable, followed by SIVmax 2800, which is lower than SIVmax 4500, which is followed by SIVmax7800 (Zone A regulatory releases >7,800 cfs from Lake Okeechobee, the highest priority variable for the Caloosahatchee). Note, however, that all these variables / performance measures are considered first order priority variables even though it is possible to rate them relatively among each other. All variables are weighted equally in the ROGEM equation.

ROGEM scores for Caloosahatchee are calculated according to the following:

1/4 (SIV*min* + SIV*max2800* + SIV*max4500* + SIV*max7800)*

Scores for all of the plans and the two base cases are presented in Table Caloosahatchee Estuary - 1. To summarize: Alternatives A through D13R all scored 1.0 on a scale of 0.0 to 1.0. The Caloosahatchee subteam agrees that any of the alternatives would be considered very good for Caloosahatchee Estuary. All the alternatives greatly exceed the target values set in the performance measures (except for regulatory releases, which meets the target). Furthermore, alternatives A through D show major improvements over the 1995 Base, which scored 0.0, and the 2050 Base, which scored 0.1. Because all but one of the regulatory releases were eliminated in plans A through D13R, SIV*max7800* was not weighted more heavily than the other variables. However, if the plans had not been so successful in eliminating the Zone A regulatory discharges then SIV*max7800* would have been weighted.

D.8.11 St. Lucie Estuary

Variables and Performance Measures Evaluation

The suitability index variables (SIVs) were developed using existing performance measures for St. Lucie Estuary. The variables / performance measures have targets based on flow that would support optimum hydrologic conditions conducive of optimum quality habitat for fish, wildlife, and other aquatic resources. The targets are based on optimization model outputs, natural variation that would occur during the period 1965-1995, and desirable salinity conditions for existing and potential aquatic resources within the St. Lucie Estuary. These are not all of the existing performance measure for the St. Lucie Estuary but are a subset selected by the St. Lucie subteam to be used to evaluate Restudy plans. There are additional performance measures posted on the Restudy web page that also provide information for the estuary. However, the additional performance measures were determined to be a lower level priority for the present Restudy evaluation and are not included in the present presentations / evaluations.

The St. Lucie Estuary River of Grass Evaluation Methodology (ROGEM) is comprised of four metrics (suitability index variables, or SIVs) that concern maintenance of desirable salinity conditions within the St. Lucie Estuary. The SIVs are based on research, empirical findings, and a hydrologic analysis of the period 1965 through 1995. The ROGEM outputs are ordinal numbers. Ordinal scores are calculated based on performance measure (PM) targets for each of the variables. The highest possible score of 1.0 represents optimum hydrologic conditions conducive of optimum quality habitat for the estuarine indicator species chosen (oysters and SAV). Decreasing scores to 0.0 represent decreasing habitat quality.

The St. Lucie Estuary receives freshwater inputs both through interbasin transfer from Lake Okeechobee and from local watershed contributions. The maintenance of flows to the estuary to achieve the appropriate salinity regime therefore must manage both watershed runoff and regulatory flows from the lake. Several performance measures from the SFWMM dealing with various inflows to the estuary were selected for ROGEM to compare alternative restoration scenarios. On the most basic level, inflow problems can be divided into two categories: 1) High inflow events, when large regulatory releases from the Lake and / or the watershed cause poor estuarine water quality and 2) Maintaining dry season base flows. Minimum levels of inflow and nutrients usually occur at the end of the dry season (April and May). It is during these months that numerous species of juvenile fish depend on an abundant food supply of phytoplankton and zooplankton, which requires a minimum level of fresh water and nutrients. In order for the estuary to act as a nursery for juvenile fish, plankton populations should be at a high enough density for fish to easily feed.

To determine appropriate water quantity inflows to the estuary, biological indicators with definable salinity preferences were chosen. A favorable range of salinities for the estuary were determined (referred to as the salinity envelope) based on the requirements of SAV and oysters. Woodward-Clyde, in a literature review report developed for the District in 1998, summarizes the approximate salinity tolerances for selected SAV and American oyster. A report on the abundance and type of SAV species by Phillips and Ingle (1960), provided the most complete source of information on SAV occurrence and abundance in the St. Lucie Estuary. This survey of SAV which was conducted from September 1957 to March 1959 revealed that the three most commonly found species of SAV in the estuary at the time were shoal grass (outer and middle estuary), manatee grass (outer estuary), and widgeon grass (north fork). They also reported on the salinity tolerance, normal, common and optimum range for all species. The normal tolerance range for shoal grass is 5-55pptt; for manatee grass, 17-44 ppt; and for widgeon grass, 0-45 ppt. These numbers were based on reviewed literature, and all species can withstand even greater salinity fluctuations for short periods of time. The salinity tolerance ranges were also summarized for the different life cycle stages of the American oyster. The optimum range for adults and juveniles is 10-20 ppt, 20-23 for spat, 23-27 for larvae and embryos and 15-20 ppt for a sustainable population (Woodward-Clyde 1998). More details can be found in tables 13-3 and 13-4 of the report. These favorable ranges of salinity (salinity envelope) have been related to volumes of freshwater flow to the estuary and a target range of flows was determined. In order to meet the salinity envelope criteria the surface water flows coming from the watershed as well as from ground water should be in the range of 350 cfs – 1,600 cfs. The ROGEM model for the estuary is based on four sets of variables (or performance measures). Each variable has an acceptable number of violations of the upper and lower flow range to take into consideration natural variation of flow.

Variables, SIVs. The ROGEM equation for St. Lucie Estuary includes the following four variables:

SIV*min* = # of months with mean monthly flow < 350 cfs
SIV*max 1600* = # of months with mean monthly flows > 1,600 cfs
SIV*max 2500* = # of months with mean monthly flows were > 2,500 cfs
SIV*max 7200* = # of days with Lake Okeechobee Zone A discharges > 7,200 cfs

Values range from 0.01 (the least desirable condition) to 1.0 (the most desirable condition).

Variable SIV*min*. This variable is based on the number of months the mean monthly flow from the lake and watershed fall below 350 cfs for the 1965-1995 period. The target is to have no more than 50 months with mean monthly flow less than 350 cfs for this period of analysis.

Principal Objective: This variable addresses the importance of low flow conditions (mean monthly flows<350 cfs). The objective is to maintain sufficient minimum mean monthly flows in order to maintain favorable conditions for estuarine organisms. This includes the importance of fresh water and nutrient input into the system in the appropriate quantity and timing to support primary and secondary productivity (discussed in more detail in the following paragraphs).

Rationale: Insufficient freshwater discharges during the dry season contribute to reduced estuarine productivity. Minimum levels of inflow and nutrients usually occur at the end of the dry season (April and May). It is during these months that numerous species of juvenile fish depend on an abundant food supply of phytoplankton and zooplankton which requires a minimum level of fresh water and nutrients. In order for the estuary to act as a nursery for juvenile fish, plankton populations should be at a high enough density for fish to easily feed.

The target salinity gradients in St. Lucie Estuary were determined by a hydrodynamic salinity model (Morris 1987) combined with estimates of salinity requirements for two indicator species in the estuary, Halodule wrightii (shoal grass) and Crassostrea virginica (American oyster). Target minimum mean monthly flows to the estuary are 350 cfs to protect oysters near the Roosevelt Bridge, promote brackish aquatic plant growth, and support juvenile fish populations. This flow could come from the watershed (including groundwater), Lake Okeechobee (via S-80), or a combination of the two.

Outputs for SIV*min*: As stated above, the ROGEM indices are ordinal rather than cardinal numbers. The total allowable number of monthly violations is based on the natural variation of hydrologic conditions during the period 1965 to 1995. The results of hydrologic modeling indicate that the optimum senario would have no more than 50 months of mean monthly flows of <350 cfs. The estuary data for the alternatives is taken from the performance measures bar graphs and tables titled "Number of times Salinity Envelope Criteria were NOT met for the St. Lucie Estuary."

The ROGEM output for this variable is calculated using the formula:

$$1 - \frac{\text{observed \# of months - target \# of months}}{\text{range (observed max \# of months for all Alts - target)}}$$

Note: The output is set at 1.0 (i.e. does not exceed 1.0) which indicates optimum conditions.

Results for SIV*min* are presented in Table St. Lucie Estuary - 1.

Variable SIV*max1600*: This variable is based on the number of months that mean monthly flow exceeds 1,600 cfs as measured from the lake and the watershed for the

1965-1995 period of record. The acceptable violations (target) allowing for natural variation is nine for the 1965-1995 period of record.

Principal Objective: Reduce high volume discharge events to the estuary to improve estuarine water quality and protect and enhance estuarine habitat and biota.

Rationale: Recent analysis has determined that mean monthly flow should not frequently exceed 1,600 cfs. As flows exceed this limit, the salinity is reduced below desirable levels for some estuarine resources. Also, high volume discharges to the estuary contribute to poor estuarine water quality including increased turbidity, and violation of the favorable salinity envelope. These events have direct effects on SAV by reducing light penetration necessary for photosynthesis, degrading fish and invertebrate habitat, and contributing to unfavorable salinity concentrations for aquatic vegetation, fish and invertebrates, including the indicator species (American oyster and SAV).

Outputs for SIV*max1600:* As stated above, the ROGEM scores are ordinal rather than cardinal numbers. The total allowable number of monthly violations is based on the natural variation of hydrologic conditions during the period 1965 to 1995. The results of hydrologic modeling of this period indicate that the optimum scenario would have no more than nine months of mean monthly flows of >1,600 cfs. The St. Lucie Estuary data for the alternatives is presented in the performance measures bar graphs and tables titled "Number of times Salinity Envelope Criteria were NOT met for the St. Lucie Estuary."

The ROGEM output for this variable is calculated using the formula:

$$1 - \frac{\text{observed \# of months - target \# of months}}{\text{range (observed max \# of months for all Alts - target)}}$$

Note: The maximum output is set at 1.0 (i.e. does not exceed 1.0) which indicates optimum conditions.

Results for SIV*max1600* are presented in Table St. Lucie Estuary - 1.

Variable SIV*max2500:* This variable measures the number of times mean monthly flows from the lake and watershed exceeds 2,500 cfs for the 1965-1995 period of record. The target is no more than three months with men monthly flows > 2,500 cfs for the 1965-1995 period of record.

Principal Objective: Reduce the occurrence of extreme discharge events and improve water and sediment quality in the estuary to protect estuarine vegetation, invertebrates, and fish communities.

Rationale: Mean monthly flows above 2,500 cfs result in freshwater conditions throughout the entire estuary causing severe impacts to estuarine biota. This volume of flow begins to impact the Indian River Lagoon to the north and south of the St. Lucie Inlet.

Outputs for SIV*max2500:* The ROGEM scores are ordinal numbers. The total allowable number of monthly violations, based on natural variation of hydrologic conditions, and hydrologic modeling of this period indicate that the optimum condition is to have no more than three months of mean monthly flows of >2,500 cfs. The St. Lucie Estuary data for the alternatives is presented in the performance measures bar graphs and tables titled "Number of times Salinity Envelope Criteria were NOT met for the St. Lucie Estuary."

The ROGEM output for this variable is calculated using the formula:

$$1 - \frac{\text{observed \# of months - target \# of months}}{\text{range (observed max \# of months for all Alts - target)}}$$

Note: Output is set at 1.0 (i.e. does not exceed 1.0) which indicates optimum conditions

Results for SIV*max2500* are presented in Table St. Lucie Estuary - 1.

Variable SIV*max7200:* This variable is based on the number of days of Zone A discharge from the Lake, (7,200 cfs per day at S-80) for each alternative for the period 1965-1995. The target is zero (0) violations. Because of the magnitude of Zone A releases on the environment, this variables is the highest priority of the four ROGEM variables and would normally have been weighted in the overall ROGEM equation. However, since alternatives A – D13R eliminate all except for two days of the Zone A releases, this variable was not weighted.

Principal Objective: Eliminate the occurrence of extreme discharge events from the lake to the estuary, and improve estuarine water quality in order to protect existing and potential habitat for estuarine vegetation, invertebrates, and fish communities.

Rationale: Zone A discharges transport large amounts of sediment and results in freshwater conditions within the entire estuary. These events can have rapid and serious effects on estuarine SAV by reducing light penetration necessary for photosynthesis, destroying fish and invertebrate habitat. They contribute to unfavorable salinity concentrations for most aquatic life, including the American oyster and SAV, as well as contributing to the occurrence and severity of fish diseases. These large volume discharges also cause adverse effects on large areas of the Indian River Lagoon surrounding the St. Lucie Inlet and possibly influence nearshore ocean habitats adjacent to the Inlet. Prolonged Zone A discharges result in even greater damage to the various ecosystems, and more widespread adverse effects.

Outputs for SIV*max7200*: No Zone A discharges of this magnitude are desirable. Furthermore, the results of hydrologic modeling of the period 1965-1995 indicate that no daily flows of >7,200 cfs would have occurred during this period. The estuary data for the alternatives is presented in the performance measures bar graphs and tables titled "Number of times Salinity Envelope Criteria were NOT met for the St. Lucie Estuary."

The ROGEM output for this variable is calculated using the formula:

$$1 - \frac{\text{observed \# of days}}{\text{range (observed max \# days for all alts)}}$$

Note: Output is set at 1.0 (i.e. does not exceed 1.0) which indicates maximum conditions.

Results for SIV*max7200* are presented in Table St. Lucie Estuary - 1.

ROGEM equation and final scores for St. Lucie Estuary

The variables can be prioritized from lowest to highest, according to the following: SIVmin is the lowest priority variable, followed by SIVmax 1600, which is lower than SIVmax 2500, which is followed by SIVmax7200 (Zone A regulatory releases >7,200 cfs from Lake Okeechoobee, the highest priority variable for St. Lucie. Note, however, that all these variables/performance measures are considered first order priority variables even though it is possible to rate them relatively among each other. All variables are weighted equally in the ROGEM equation.

ROGEM scores are calculated according to the following:

1/4 (SIV*min* + SIV*max1600* + SIV*max2500* + SIV*max7200)*

Scores for all of the plans and the two bases are presented in the attached table. To summarize: alternatives A through D all scored 0.8 on a scale of 0.0 to 1.0. The St. Lucie subteam agrees that any of the alternatives would be considered fair for St. Lucie Estuary. The principle reason for this is that the basin runoff results are still about 4 times greater than their targets. The reason that the ROGEM score was 0.8 was because the regulatory release and low-flow targets were almost met.

While there is very little difference between alternatives A through D they all show improvements over the 1995 Base, which scored 0.0, and the 2050 Base, which scored 0.1. Because most regulatory releases were eliminated in plans A through D, SIV*max7200* was not weighted more heavily than the other variables. However, if the plans had not been so successful in eliminating the Zone A regulatory discharges then SIV*max7200* would have been weighted.

In Alternative D13R, for flows <350 cfs, (target = 50), the performance was 51. For flows >1,600 cfs, (target = nine), the performance was 15. For flows >2,500 cfs, (target = five) and the performance was eight. These output values are a vast improvement over the previous alternatives. As for grades and color codes; the grade would be a B+ and the color would be green.

D.8.12 Lake Worth Lagoon

The performance measure used in this analysis for the Lake Worth Lagoon was “Wet/Dry season average flows discharged to Lake Worth Lagoon through S-40, S-41, and S-155 for the 31 year simulation.” The restoration target is to create estuarine conditions, to the extent possible, in the Lake Worth Lagoon. An estuarine salinity envelope of 23 ppt to 35 ppt has been chosen as the target salinity range. This is a viable salinity range for a number of organisms many of that are commercially and recreationally important. To attain this salinity a maximum flow needed to be developed. Previous hydrodynamic modeling displayed that 500 cfs creates a steady state salinity of 23 ppt. For the low flow part of the salinity envelope, 0 cfs is the target. Enough ground water occurs that should still allow estuarine conditions. Based on past modeling, this flow range of 0-500 cfs should create the salinity range of 23 ppt - 35 ppt.

The following protocol was used for the Lake Worth Lagoon:

Ranking: The alternatives and bases were ranked from 1-5 (one being best, see Table Lake Worth Lagoon - 1). Alternatives A, B, C, D, and the 2050 Base were ranked. The rankings for the two performance measures were added and Alternative B was best, followed by C, than D and A, and lastly the 2050 Base. After closely examining the model output, the minimum flow performance criteria for D has a number of small releases that are above 0 cfs, but small enough that they do not effect the estuaries salinity. So in actuality D is probably tied with C in the ranking.

Colors: None of the alternatives were colored green. Alternatives B, C, and D were colored yellow and A, 2050 Base, and 1995 Base were colored red.

Grades. Alternative B was graded a B, alternatives C and D were graded a C, Alternative A was a D, and the 2050 Base and 1995 Base were graded an F. Once again, Alternative D was probably very close to a B after reviewing the model output.

Alternative D13R has the same numbers as D and so would be ranked, colored, and graded the same.

Table Caloosahatchee Estuary

Variables (from PMs) **Caloosahatchee Estuary ROGEM Values (based on PMs)**

D.8.13 Biscayne Bay Surface Water Matrix Documentation

Geographical Region

For the purposes of this evaluation, Biscayne Bay is considered to be bounded by Snake Creek to the north (Oleta River State Park) and the southern border of Biscayne National Park to the south. Influence of proposed water management alternatives on Card and Barnes sounds to the south of Biscayne Bay will be considered as part of the Model Lands Other Project Element.

Derivation of Performance Measures

Based on historical accounts and scientific studies, Biscayne Bay has been classed as a positive, shallow, tidal, bar-built estuary (Kohout and Kolipinski 1967). The term positive refers to the condition of salinity being less than seawater (Hela et al. 1957). The salinity gradient that established estuarine habitat in Biscayne Bay is dependent on both surface and ground water flows (Fatt and Wang 1987). The effect of regional drainage projects on these flows has been to disrupt salinity patterns and impair coastal ecosystem function by altering the timing and amounts of freshwater input to the bay.

Historically (pre-1910), freshwater input to the bay was through numerous coastal streams, sloughs, and springs and from wet season sheetflow flow to the tidal zone. Currently, ground water and surface water flow to the bay that contributed to estuarine salinities is reduced and hydroperiods have been altered. Surface water input to the bay is now intercepted and delivered through 14 regulated canals that are characterized by high amplitude, short duration storm flows during the wet season and low base flow during the dry season.

While accomplishing the goal of flood control, the presence and operation of the canals has had profound hydrological and ecological consequences on Biscayne Bay (Teas et al. 1976, Thorhaug et al. 1976, Hoffmeister 1974). The temporal and spatial pattern of freshwater inflow to the bay was fundamentally altered to one of point source discharges (canal mouths) that are characterized by abrupt periods of high discharge and minimal or no discharge to the bay. Although the general pattern of wet and dry seasons still persist, operation of coastal water control structures results in rapid changes in local salinity gradients that may occur on a daily basis and over several months, particularly during the rainy season (Fatt 1986). During the dry season, hypersalinity has been observed as a result of evaporation, retention of canal flow, and bay circulation (Lee 1975). While abrupt changes in salinity can occur naturally in nearshore habitats, they usually result from infrequent events such as hurricanes and tropical storms. The effects of salinity changes have been documented for fish (e.g. Davenport & Vahl 1975, Provencher et al. 1993, Serafy et al. in press) and for invertebrates (e.g. Brook 1982, Montegue and Ley 1993, Irlandi et al. in press). The presence and operation of the canals and construction of permanent oceanic inlets has resulted in a loss of estuarine function and shifted Biscayne Bay to more of a lagoon, adversely impacted from freshwater pulses and highly variable salinities. These conditions have been at least partly responsible for the loss of historically abundant estuarine species, such as red drum, black drum, and eastern oyster, the loss of juvenile fish habitat, and the significant increase in stress-tolerant fish species such as the gulf toadfish (Serafy et al., in press).

Biscayne Bay ecosystem restoration plans were initially considered by the South Florida Water Management District in a planning process that resulted in a water management plan, Surface Water Improvement and Management Plan for Biscayne Bay (SWIM Plan, Alleman 1995). This document provides a detailed discussion and analysis of water management needs in the Biscayne Bay watershed, including initial restoration plans for canal flow redistribution. It clearly outlines the rational for 1) reducing excessive canal discharges by flow management, 2) providing a stable brackish water habitat during the wet season, and 3) providing more water during dry periods to prevent hypersaline conditions from impacting important marginal wetlands and nearshore habitats. It also outlines research needs to further refine restoration designs and actions. Based on this plan and the consensus of government resource managers and university researchers, performance measures that would promote restoration of the Biscayne Bay ecosystem were established to permit evaluation of proposed water management alternatives.

Performance Measures

Performance measures were developed based on the potential effect of water management alternatives on surface water reaching Biscayne Bay. Canal discharges from gauged structures on canals that discharge into the bay were used. Based on SFWMM hydrologic model output, the bay was divided into five regions from north to south, based on the mean monthly discharge from water control structures in these regions. The regions were Snake Creek (S29), North Bay (G58, S28, S27), Miami River (S25, S25B, S26), Central Bay (G97, S22, S123), and South Bay (S21, S21A, S20F, S20G). Model output for each alternative provides results as the sum of discharge from the structures in each region in terms of a mean annual wet season and dry season volume. To judge the performance of a water management alternative in meeting restoration targets, model results were compared to surface water budget targets that were considered appropriate to achieving restoration of the Biscayne Bay ecosystem. These targets consist primarily of the existing average annual inflow to Biscayne Bay as defined by the 1995 Base hydrologic period, with a 2% increase in total inflow budget to be applied in the dry season to the Central and South Bay regions. A separate target for Snake Creek (S29) was also developed based on canal discharge that would maintain salinities for oyster survival.

Performance of individual alternatives was scored by comparing the predicted mean annual discharge for each alternative to the appropriate target for each region. A straight proportion of achieving the target was used to represent the degree to which the alternative achieved the target value, scaled from 0.0 to 1.0, for wet season, dry season, and for the total mean annual flow for that region. In instances for which an alternative exceeded the target, the score was automatically set to 1.0. An overall (total) bay performance measure was calculated using the total bay inflow from each of the regions defined by the SFWMM model.

Performance Evaluation

The scores in the following matrix are to be used only to rank the performance of the regional water management alternative in terms of supplying surface water to Biscayne Bay. They assume all components, especially the use of 're-use' water in alternatives C and D, are present. This refers to the use of 're-used' water or tertiary-treated domestic wastewater to replace water that will be withdrawn from the existing water management plan. The assumption that is implicit is that 're-used' water will be both available and appropriate for use in a valuable, pristine, marine environment that sustains Biscayne National Park. Additional feasibility studies must be pursued and completed before any component of an alternative will be considered appropriate. The use of this matrix does not constitute endorsement of any of the alternatives.

Biscayne Bay currently receives surface water in amounts that will, when properly distributed, permit partial restoration of the coastal ecosystem. Therefore, matrix scores for the bay that are less than 1.0 indicates a potential adverse impact to wildlife and fishery resources in the bay and in Biscayne National Park. Alternative D performs the best in terms of available water, but in terms of total bay inflow, Alternative D does not improve conditions for restoration beyond currently existing (1995 Base) conditions. As such, all alternatives currently proposed are considered as having a negative effect on the potential of achieving restoration of the Biscayne Bay ecosystem.

The following is a summary of water management alternative performance scores based on a comparison between SFWMM model output and restoration targets for mean annual surface water budgets for bay regions and for the total bay freshwater input.

Biscayne Bay Water Management Performance Scores

	1995 Base	2050 Base	Alternative A	Alternative B	Alternative C	Alternative D
North Bay						
Dry Season	1.00	0.90	0.51	0.93	0.93	0.93

Biscayne Bay Groundwater Matrix Documentation

Groundwater Index

The index is the measure of the degree to which groundwater levels produced by each alternative match projected comparison conditions (NSM = primary comparison, Ghyben-Herzburg relationship for that indicator region = minimum target). Groundwater flows into Biscayne Bay are potentially important as a source of freshwater. Under conditions where high water stages occurred west of the Atlantic Coastal Ridge to within three miles of Biscayne Bay, historic groundwater flows were sufficient to support flowing springs that allowed the collection of drinking water for ships (Parker et al. 1955). Present day rates of groundwater discharge are evidently insufficient to produce such flowing springs (Mulliken and VanArman 1995). The desired groundwater levels for restoration are those that match historic conditions. The minimum acceptable groundwater levels to support the Biscayne Bay estuary are those sufficient to eliminate salt water intrusion to the Biscayne Aquifer, as theoretically measured by the Ghyben-Herzburg relationship.

The groundwater indicator regions are located at the edge of the SFWMM grid, and output results for NSM are, therefore, not accurate. They do, however, provide a relative measure for current vs. historical groundwater levels and are, therefore, a reasonable approximation for the direction in which groundwater levels should be restored in order to return historic groundwater flows to Biscayne Bay.

Since groundwater values were normalized to ground elevation, they are negative numbers and direct comparisons are difficult. Two indices were defined, therefore, to create proportional relationships that could be compared. The first index looks at the midpoint of the stage duration curve, and the second index uses the values representing the 90^{th} percentile of the stage duration curve. The midpoint was chosen to give an indication of the relative performance of the alternatives under moderate conditions. The 90^{th} percentile comparison gives an indication of the relative performance of the alternatives under severe drought conditions. NSM values consistently represented the wet extreme of the modeling scenarios, and one or more alternatives represented the dry extreme. The index sets up a comparison between the absolute difference between a particular alternative and NSM and the absolute difference between the dry and wet extremes, i.e. the worst alternative and NSM.

Indicator Regions Covered: 48, 49, 50, 51

Formula

The following formula sets up a proportional relationship showing the relative wetness of the alternative when compared to the range available. The index values vary from 0.0 to 1.0, with 1.0 equal to NSM conditions and 0.0 equal to the worst alternative.

Groundwater Index 1 = 1 - [(alternative value at 50% mark of stage duration curve)-(NSM value at 50% mark of stage duration curve)]/[(worst alternative value at 50% mark of stage duration curve)-(NSM value at 50% mark of stage duration curve)]

Minimum Target 1 = 1- [(low water target value for indicator region)-(NSM value at 50% mark of stage duration curve)]/[(worst alternative value at 50% mark of stage duration curve)-(NSM value at 50% mark of stage duration curve)]

Groundwater Index 2 = 1 - [(alternative value at 90% mark of stage duration curve)-(NSM value at 90% mark of stage duration curve)]/[(worst alternative value at 90% mark of stage duration curve)-(NSM value at 90% mark of stage duration curve)]

Minimum Target 2 = 1 - [(low water target value for indicator region)-(NSM value at 90% mark of stage duration curve)]/[(worst alternative value at 90% mark of stage duration curve)-(NSM value at 90% mark of stage duration curve)]

Note: For Indicator Region 51 (South Biscayne Bay), the NSM value was less than the low water target at the 90^{th} percentile, so the equation for this indicator region was changed to use the low water target as the standard for comparison. The equation for this indicator region was:

Groundwater Index 2 (IR51) = 1 - [(alternative value at 90% mark of stage duration curve)-(low water target for IR51)/(worst alternative value at 90% mark of stage duration curve)-(low water target for IR51)]

The minimum index for comparison was:

Minimum Target 2 (IR51) = 1 - [(low water target value for IR51)-(low water target for IR51)]/[(worst alternative value at 90% mark of stage duration curve)-(low water target for IR51)]

Summary Matrix

The summary matrix was derived by averaging the results from each indicator region for each alternative. Values for the Central and South Biscayne Bay indicator regions (IR50, IR51) were weighted more heavily in the analysis by adding them twice into the average. This weighting system was selected to give priority to alternatives that improved conditions within Biscayne National Park. NSM values were not included because NSM values were presented for comparison purposes only; it is not a target.

Interpretation

The matrix for the 50th percentile of the stage duration curves shows almost no difference among the alternatives. The raw index scores varied from 0.000 to 0.080 on a scale of zero to one. None of the alternative scores exceeded the low water target for that region, although Alternative D in Indicator Region 50 came closer than any other scenario. For three of the four indicator regions, the 1995 Base condition was the best among the alternatives. When the indices were averaged, 1995 Base conditions were slightly better than alternatives C and D, though the separation among the three was very small. These results indicate that under average conditions, almost nothing in the Restudy has had any effect on groundwater elevations near the Atlantic Coastal Ridge, and nothing proposed to date in the Restudy has made any difference with respect to restoring groundwater flows to Biscayne Bay. Results for Alternative D13R were identical to those for Alternative D.

The matrix for the 90th percentile of the stage duration curves shows some differences among the alternatives. The 90th percentile represents conditions of severe drought, and any improvement in this part of the curve over base conditions would probably mean some maintenance of groundwater flows under drought conditions. The raw index scores varied from 0.000 to 0.463, with the low water target index at 1.000 for comparison. The alternative with the best scores varied by indicator region, but the 1995 Base, Alternative C and Alternative D were usually close, except for Central Biscayne Bay (IR50), where the 1995 Base was clearly the worst alternative. Alternative B produced moderately good results for Indicator Region 48 and Indicator Region 50. When the indices were averaged, however, alternatives C and D came out much better than base conditions or Alternative B, with Alternative D performing slightly better than Alternative C. The provision of additional water appears to help maintain groundwater levels in the region during extreme drought conditions, and may play an important role in maintaining some degree of groundwater flow to Biscayne Bay during periods of extreme drought. Results for Alternative D13R were identical to those for Alternative D.

It should be emphasized that these conclusions were made on the basis of a very small improvement to groundwater conditions under severe drought conditions. None of the alternatives come close to meeting the minimum water level targets set for the indicator regions. The overall conclusion must be that although Alternatives D/D13R perform better than the other alternatives, nothing proposed to date in the Restudy has made a significant difference with respect to restoring groundwater flows to Biscayne Bay. It is hoped that additional means for improving groundwater flows will be sought and implemented as part of the design phase of the project.

Notes on Biscayne Bay Groundwater Matrix Interpretation

It is clear from these results that additional water sources can make a noticeable contribution toward maintaining groundwater levels for Central and South Bay during drought conditions. These results mirror effects seen in the surface water output. The source of the water is, however, a concern. Treated wastewater has not yet been unequivocally shown to be an economically and environmentally feasible alternative, and dependence upon this source to supplement water supplies to the bay could prove short sighted, should it be eliminated as a source in the future. It is strongly recommended, therefore, that alternative sources of water be identified during the design phase that could be used to provide water deliveries for the bay.

Notes on Biscayne Bay Surface Water Matrix Interpretation

The alternative analysis has only addressed surface water timing issues in a very superficial manner and only in the vicinity of Biscayne National Park. More needs to be done to address this problem in the more urbanized areas of the bay.

The alternative analysis has not adequately addressed water quality issues for either surface water or groundwater moving to the bay. In areas where less surface water is delivered to the bay via canals, pollutants from urban sources are likely to increase in concentration. This is a particularly formidable problem in the Miami River, where the source for many pollutants is well downstream from where water is being stored (the Lakebelt Reservoir). By the time the river water is discharged into the bay, the large reduction in volume may result in a substantial increase in pollutant concentration. More attention should be given to addressing such concerns prior to finalizing a project design.

Biscayne Bay Evaluation Matrix, by Indicator Region, Final Draft 7/31/98

Values vary from 0 to 1, with larger values preferred. Preferred alternatives produce index values greater than the minimum index value for that percentile.

D.8.14 Keystone / Endangered Species / ATLSS

Performance Based Comments

For Alternative D13R ATLSS high resolution hydrology results and breeding potential index, individual-based simulation and Population Viability Analysis results for the Cape Sable seaside sparrow are available. Fish abundance, snail kite foraging conditions index, wading bird foraging conditions index and white-tailed deer breeding potential index results are presented. American crocodile performance measure results are also presented.

Fish

The ATLSS fish model results have consistently predicted higher overall fish abundances as flow volume and inundation duration have moved closer to NSM conditions. Continuing this trend, ATLSS results suggest that Alternative D13R hydrologic conditions should produce average fish abundances higher than those expected for 2050 Base, and slightly higher than other alternatives as expected hydroperiods increase consistent with NSM. In particular, increased hydroperiods in NE Shark River Slough, Taylor Slough, WCA-3B, northeast WCA-3A, and WCA-1 should lead to greater fish abundance. This is also true when only prey-sized fish at appropriate wading bird foraging depths are counted except for the deepest parts of Shark River Slough and WCA-3B.

Wading Birds

Alternative D13R reduces many of the excessive high water conditions and excessive inundation durations that had caused concern for eastern WCA-3A, southern WCA-3A and WCA-3B in several previous alternatives. These improvements should provide relatively larger areas suitable for wading bird foraging and decreased flood-induced losses of wading bird nesting substrates in WCA-3 under Alternative D13R as compared to Alternative D. When compared to the 2050 Base, Alternative D13R provides mixed results for wading birds in WCA-3, with improvements in southern WCA-3A (due to reduced high water) and in northern WCA-3A (due to reduced drydowns), and losses in northeastern WCA-3A and WCA-3B (due to increased high water).

Results for the southern Everglades and for Florida Bay also indicate that Alternative D13R better matches natural conditions in these areas than other alternatives. The improvement in the timing and duration of freshwater flows to Florida Bay estuaries and improved timing of food-concentrating drydowns should lead to better wading bird foraging and breeding conditions in the southern Everglades under Alternative D13R relative to both base cases. Greater fish abundances expected under Alternative D13R, as compared to the 2050 Base, also suggest improved foraging conditions for wading birds.

Wood Storks

ATLSS long-legged wading bird results and a wood stork performance measure recently developed by John Ogden are used to evaluate wood stork responses under Alternative D13R. Both the ATLSS high resolution hydrology results and inspection of the Shark Slough inundation duration and mainland estuary flow volume information used in the performance measure reveal significant improvements in hydroperiods, volume and timing of flows under all alternatives, including Alternative D13R as compared to 2050 Base. This should provide significantly improved forage availability in the Florida Bay estuaries that historically supported the majority of wood stork nesting, and may result in beneficial earlier nest initiation cues for wood storks. Comparison of Alternative D13R with Alternative D provides mixed results, with improved inundation duration in Shark Slough Indicator Region 10 but not Indicator Region 9, and no significant difference for freshwater flows to Florida Bay estuaries. Therefore, Alternative D13R cannot be distinguished from alternatives A-D in terms of wood stork habitat suitability.

Snail Kites

In general, comparison of hydrology expected under Alternative D13R vs. the 2050 Base shows significant progress toward natural conditions represented by NSM. Such a shift towards more natural conditions produces a slight improvement in overall foraging conditions for snail kites due to an overall increase in extent of longer hydroperiod areas conducive to apple snail production, and a reduction in artificially impounded areas having persistent deep water that causes long-term loss of snail kite nesting substrates. Snail kite foraging habitat would probably shift from some current high-use areas such as WCA-2B and southern WCA-3A to central and eastern WCA-3A, northern WCA-3B and the flanks of Shark River Slough where Alternative D13R would provide longer hydroperiods suitable for sustained apple snail production. Benefits would be particularly apparent in low water years due to the overall increase in water available to the natural system under Alternative D13R and the snail kite's particular sensitivity to reduction of suitable foraging habitat during drought. Benefits to snail kites under Alternative D13R cannot be distinguished from those expected under alternatives C and D. Expected benefits under Alternative D13R would probably not influence long term trends in the overall snail kite population because other habitats, outside the area modeled for Restudy alternatives, are thought to be more important to the species as a whole.

White-tailed Deer

Alternative D13R reduces many of the excessive high water conditions and excessive inundation durations that had caused concern for eastern WCA-3A, southern WCA-3A and WCA-3B in several previous alternatives. These improvements provide slightly better foraging conditions and reduced drowning losses for white-tailed deer in WCA-3 under Alternative D13R as compared to Alternative D. Overall increased hydroperiods in most of the WCAs and northeastern Big Cypress under Alternative D13R as compared to the 2050 Base would slightly decrease habitat quality in these marginal deer habitats. Small areas of northeastern and southern WCA-3A and the Big Cypress-ENP border area are exceptions. Alternative D13R continues progress towards NSM-like conditions in most of ENP and would be expected to continue to produce reduced white-tailed deer habitat suitability in many already poor deer habitats there. For those few areas with high deer breeding potential (Long Pine Key and surrounding short hydroperiod marsh and NW Big Cypress), there is little difference between Alternative D13R and the 2050 Base.

Florida Panther

Review of the Alternative D13R ATLSS high resolution hydrology results shows that no change is expected in the higher elevation pine flatwood and hardwood hammock habitats preferred by Florida panthers. Additionally, discussions with panther experts Dennis Jordan and Sonny Bass (personal communications, June 1, 1998) indicate that slight reductions in the quality of already poor deer habitats, as expected under Alternative D13R, would not have an effect on panther populations.

Cape Sable Seaside Sparrow

Predicted results for Alternative D13R rely on ATLSS modeling results and April 24 and June 1, 1998, discussions with species experts Stuart Pimm, Sonny Bass, Phil Nott, and John Curnutt.

ATLSS Breeding Potential Index results showed consistently lower breeding potential for Cape Sable seaside sparrows in eastern habitats and in the southeastern part of the western subpopulation habitat under Alternative D13R as compared to Alternatives B, D and the 2050 Base. However, the sparrow Breeding Potential Index does not take population dynamics or fire return frequencies into account. When reductions in damaging fire return frequencies in the sparrow's eastern habitats expected to result from hydroperiod increases like those in Alternatives B-D and D13R are factored in, these alternatives are likely to significantly improve sparrow habitat suitability in the eastern marl prairie areas. The central population is unlikely to be affected by any of the alternatives due to its higher elevation.

The ATLSS individual-based sparrow model includes detailed simulations of population dynamics, and therefore provides better information on the expected effects of management scenarios than does the Breeding Potential Index. The ATLSS individual-based sparrow simulation is applied only to the western sub-population, and predicts persistence of this sub-population under Alternative D13R and the 2050 Base. Alternative D13R produced higher population levels and a lesser risk of extirpation than alternatives B and D. A Population Viability Analysis using the individual model predicts that the western subpopulation will be more likely to remain above minimum numbers and reach or exceed maximum numbers under Alternative D13R than under alternatives Band D or either base.

Overall, Alternative D13R should improve conditions for the Cape Sable seaside sparrow as compared to the 2050 Base, and will likely contribute to the recovery of this subspecies.

American Crocodile

The Crocodile habitat suitability performance measure shows that Alternative D13R would produce significantly lower salinity ranges in important Florida Bay crocodile habitats as compared to the 2050 Base. This should provide improved nursery habitat availability for hatchling crocodiles and increase availability of low salinity habitats preferred by adult crocodiles. These results are not distinguishable from those for alternatives A-D.

Performance Measures and Indicators Used

ATLSS High Resolution Hydrology
Breeding Potential Index for the Cape Sable seaside sparrow
Foraging Conditions Index for the snail kite
Foraging Conditions Index for short and long-legged wading birds
ATLSS Cape Sable seaside sparrow Individual-based Simulation
ATLSS Cape Sable seaside sparrow Population Viability Analysis
ATLSS Fish Model
American Crocodile Performance Measure
Wood Stork Nesting Patterns Performance Measure

Recommendations

Continue development and use of ATLSS modeling as a tool for further planning, design and adaptive management.

Subteam Issues

The sparrow west indicator region shows that NSM predicts longer hydroperiods in the western sub-population area that would lead to further declines in sparrow habitat suitability. The subteam urges Restudy participants to reconsider NSM-based targets when biological information, such as sparrow breeding needs, suggests different targets.

Table - ATLSS and Listed Species

Summary Table for ATLSS & Listed Species Rankings

Wading Birds	5	3	3	1	1	1
Fish	5	3	3	1	1	1

D.8.15Water Quality

For each of the alternative plans A – D13R, plan components were examined to identify potential water quality impacts or benefits resulting from the operation of that component and the regulatory or ecosystem management programs affecting the future implementation of the component. The Water Quality subteam considered in detail existing federal, state, and Tribal water quality regulatory programs in the study area. Specific issues which were considered by the Water Quality subteam during evaluations of alternative plans include numeric and narrative water quality criteria, designated uses of source and receiving water bodies, special classifications (e.g., Outstanding Florida Waters), and existing and projected pollution loads.

In addition, an evaluation of the effect of Restudy alternative plans on hydraulic and phosphorus loads into and predicted performance of the Everglades Construction Project was performed by William W. Walker, Jr. (Walker, 1998) using hydrologic outputs of the South Florida Water Management Model. The Water Quality subteam also utilized hydrologic outputs from the South Florida Water Management Model to evaluate the extent of hydrologic change and corresponding water quality impacts or benefits resulting from the implementation of the alternative plans in other sub-regions of the study area. It should be noted that the subteam was not able to empirically evaluate the effect of Restudy alternatives on water quality conditions in the Big Cypress basin or the Holey Land and Rotenberger Wildlife Management Areas. For those areas, a qualitative assessment was made based upon the proposed operation of the components contained in the alternatives.

Alternative plans A – D13R and the 1995 and 2050 base conditions were compared. A ranking matrix was prepared which indicated the relative performance of the base conditions and the alternative plans utilizing the key water quality performance measures and indicators identified by the Water Quality subteam (see Table X). The subteam concluded that from a water quality perspective, Alternative D13R was preferred over Alternatives B, A, and C. The 1995 Base and the 2050 Base alternatives were not acceptable from a water quality perspective. Alternative D13R was preferred over the other alternatives based primarily on improved results for key performance indicators in Everglades National Park, the St. Lucie River estuary, and the Lower East Coast.

Specifically, for Everglades National Park, the structural phosphorus load delivered into the Park calculated by the EWQM was “zero” for Alternatives D13R and B due to decompartmentalization features of those alternatives. The Water Quality subteam determined that this was a preferred condition for the Park. For the St. Lucie River estuary, regional storage volume and modifications to the operation of the regional water supply system were optimized in Alternative D13R to achieve hydrologic targets in the St. Lucie River estuary. In the Lower East Coast sub-region, the pollutant attenuation functions of selected reservoirs (as expressed by the reservoir hydrographs and stage duration curves) was best in Alternative D13R.

TABLE
Restudy Water Quality Subteam's Combined Ranking Matrix
Recommendations/Comments to the Restudy Team

The base conditions and alternative plans were ranked on a scale of 1-7, with higher scores indicating a more preferred condition from a water quality perspective.

Subregion	95B	50B	A	B	C	D	D13R
1. Lake Okeechobee (see footnote 1)	2.5	2.5	2.5	6.5	4.5	6.5	4.5
2. EAA/ECP	1	3.5	7	6	3.5	2	5
3. WCAs 2 & 3 (see footnote 3)	1	6	7	2	3	4.5	4.5
4. St. Lucie Watershed	1	2	3.5	3.5	5	6	7
5. Caloosahatchee Watershed	1.5	1.5	3	4	5	6.5	6.5
6. LNWR	1	2	5	5	5	5	5
7. ENP	1.5	5	3.5	6.5	1.5	3.5	6.5
8. LEC (see footnote 4)	4.5	4.5	1	2	3	6.5	6.5
Cumulative Score	***14***	***27***	***32.5***	***35.5***	***30.5***	***40.5***	***45.5***

FOOTNOTES

Ranking of alternatives for Lake Okeechobee is based on evaluation of selected performance indicators. Comparing alternatives, differences greater than one percent in relative performance calculated by the model were assigned different ranks. Although the differences between simulated conditions for the alternatives are within the uncertainty of the model, the Water Quality Team felt it was important to rank the plans for Lake Okeechobee from a water quality perspective.

Water Conservation Areas 2 & 3 rankings were weighted to account for relative size (acreage).

Ranking of the alternatives based on an evaluation of potential water quality impacts/benefits in the LEC is primarily based upon salinity targets in Lake Worth and Biscayne Bay. The presumed water quality benefits resulting from an evaluation of the hydraulic performance of selected reservoirs were also evaluated. For those performance indicators, a score of zero was assigned to alternatives for which no hydraulic performance for the reservoirs was observed.

Recommendations/Comments to Restudy Team

From a water quality perspective, Alternative D13R was preferred over Alternatives B, A, & C. The 95 Base and the 50 Base were not acceptable.

The Water Quality Team determined that the Base Conditions and alternative plans should not be ranked based upon the U. S. Environmental Protection Agency's preliminary mercury model results (model needs further development). Atmospheric deposition is the dominant contributor of mercury in the Everglades Protection Area. Restudy alternative plans are not expected to significantly affect mercury in the Everglades Protection Area.

Due to a lack of model results (particularly Everglades Landscape Model results), Restudy alternative plans could not be ranked based upon water quality impacts or benefits in Big Cypress National Preserve and the Holeyland and Rotenberger Wildlife Management Areas.

D.9 SUMMARY REPORT OF SCENARIO D13R4

The Alternative Evaluation Team conducted a preliminary evaluation of the D13R4 scenario during a meeting of the full AET on 20 January 1999. The objective of this modeling exercise was to determine the feasibility of improving D13R, by capturing additional surplus water from the amount discharged to tide each year, and of conveying that "new" water (plus redistributing excessive water in the Water Conservation Areas) to better meet performance targets in the natural system. Scenarios designed to convey urban runoff water into the natural system have not previously been considered during the lengthy AET/ADT plan formulation process. The D13R4 scenario reported on here was clearly the most successful of four scenarios (R1–R4) that were developed during an intensive, multi-agency planning and modeling process, which began in November 1998.

The AET found that the overall performance of Scenario D13R4, as modeled on 13-14 January, included both gains and losses when measured against the 1995 base, 2050 base, and D13R conditions. D13R4 captured an average of 245,000 acre feet/year of new water for the natural system from Palm Beach and Broward counties. This new water, combined with excessive water from the WCAs, provided an average of 271,000 acre feet of new water each year to Everglades National Park and an average of 77,000 acre feet of new water to Biscayne Bay each year. The increased annual mean flows to the park and Biscayne Bay are expected to produce substantial improvements towards meeting the hydrological performance targets for these two areas. Although D13R4 also provided modest improvements in northeast WCA 3A and northeast 2B, by reducing the number of undesirable high water events in these two subregions, this scenario increased the number of undesirable high water events in WCAs 2A and 3B to a level greater than that predicted for the two base conditions. D13R4 also created undesirable increases in the depth and duration of flooding in the Pennsuco wetlands. By delivering urban water to the natural system, this scenario raises a number of new water quality questions.

The AET recognizes that much new information regarding the potential performance of D13R was gained during the modeling of the four scenarios R1-R4 of D13R. The hydrological responses during the modeling of these four scenarios convincingly demonstrated the operational flexibility of D13R, and offers encouraging documentation that additional improvements can be achieved during the detailed planning phases of the restoration program.

The AET recommended that the specific features of D13R4 that allowed for the capture and conveyance of substantial amounts of new water for the natural system be incorporated into the Recommended Plan, D13R, contingent upon:

- finding ways to reduce the number of damaging high water events in WCA 2A and 3B to a level at or below the level predicted for D13R;
- adequately treating the stormwater runoff from the C-51 east/C-13/14 basins directed into the Everglades Protection Area to meet all state and federal water quality standards to enable ecological restoration to be achieved; and
- moderating excessive high water events in the Pennsuco wetlands.

It was agreed that these concerns can best be resolved during the finer scale modeling and planning which will occur as a part of detail design work. The addition of these features should allow greater operational flexibility during future efforts to improve the overall performance of D13R. An issue paper may be required from the Restudy's water quality team, to more fully explore the questions being raised by the use of urban water to meet natural system targets in Everglades National Park.

D.9.1 AET Subregional "Bullet" Summary Evaluations of D13R4:

Water Quality

For the first time, 245,000 acre feet/year of urban runoff was captured, treated, and sent into the natural system to augment flows to Everglades National Park and Biscayne Bay, raising the following questions:

D13R4 assumes that the technology exists for treating urban stormwater for a whole suite of water quality parameters beyond nutrients.

There may not be sufficient land available to adequately treat the volume of wet season runoff this scenario requires.

Due to complex pollutant loads associated with urban runoff, future permitting of new discharges of treated urban runoff to Outstanding Florida Waters (ENP & Biscayne Bay) is expected to be difficult for the responsible regulatory agencies.

The additional treatment and routing facilities add a new layer of complexity to the sequencing of the implementation plan

Benefits of the new water will not be seen until all necessary water treatment components are up and running.

Total System

Connectivity was similar to D13R except for an increase in extreme depth differences between WCA-2 and WCA-3.

Sheetflow in WCA-2B showed an NSM-like pattern for the first time. Flows also improved across Tamiami Trail east of L-67 and the eastern part of Everglades National Park.

Fragmentation was the same as D13R. No additional canals and levees were removed within the natural system.

Northern Estuaries

Caloosahatchee: No change.

St Lucie Estuary: One additional discharge event over the 31-year period of record.

Lake Worth: Far fewer adverse discharges of fresh water.

Lake Okeechobee

No change.

Lower East Coast

Water supply performance is the same as D13R except there are two additional months in Broward County of low water conditions along the coast in the 31-year period of record.

Northern and Central Everglades

Eastern and northeastern WCA-3A and WCA-2B are better, but still far from the NSM envelope. New problems arose in WCA-2A and WCA-3B. The modest benefits were seen in some of the more degraded areas but serious problems developed in more pristine parts of the system.

Southern WCA-2A: Much worse than all plans and base conditions in extreme high water and extreme low water conditions. Increasing the flows through WCA-2A during the wet season only raised depths without helping increase hydroperiods into the dry season.

WCA-2B: Extreme lows improved in the northern part, extreme highs increased slightly in some areas and there were substantial improvements in hydroperiod. Part of WCA-2B is approaching NSM-like conditions; the rest is still outside the NSM envelope.

Eastern WCA-3A: General improvement in extreme high water conditions, particularly the area east of the Miami Canal. South of Alligator Alley, high water conditions are still poor. Extreme low water conditions did not change. The area is still outside the NSM envelope for both high and low water extremes.

WCA-3B: High water conditions worsened. In the west, they are worse than the 1995 base, in the east they are worse than both bases. Both the frequency and depths of high events are far outside the NSM envelope for any NSM landscape. This problem must be resolved.

Pennsuco

Both water levels and hydroperiods worsened relative to D13R. Water levels in the Pennsuco increased sufficiently higher to present a threat to tree islands.

Biscayne Bay

An additional 77,000 acre feet/year of water was sent to Biscayne Bay, greatly improving conditions. Flows could be balanced better between parts of the bay but there is obviously the flexibility within the plan to do so.

With some minor redirection of wet season flows between Central and South Biscayne Bay, D13R4 could meet targets in Central and South Biscayne Bay without reuse water from the proposed South Miami-Dade coastal reuse facility.

Model Lands

D13R4 slightly increases water levels in coastal wetlands, particularly east of U.S. 1 during the dry season.

Big Cypress

No change from D13R. Some water that used to flow west toward Roberts Lake Strand under NSM conditions still tends to move east as it did in D13R, apparently because of topography differences between NSM and SFWMM in the jetport vicinity. This is not good, but not a major problem.

Southern Everglades

D13R4 delivered 271,000 acre feet/year of "new" water to Everglades National Park and performance measures closely approached targets for Shark River Slough and the Florida Bay coastal basins and exceeded targets in Rockland Marl Marsh.

Endorsement of D13R4 by the AET regarding benefits to the southern Everglades should be strongly conditional on reversing potentially damaging effects to WCA-2A and WCA-3B and on providing adequate water quality treatment during detailed design and modeling.

Endangered Species

Preliminary analysis shows no change to Cape Sable Seaside Sparrow, maybe a slight improvement for eastern populations.

Improved conditions for wood storks, crocodiles, and manatees.

ATLSS modeling results may show some snail kite concerns.

D.9.2 Uncertainties

The NSM topography in NE Shark River Slough is assumed to be the same as current topography, although recent data collected by EPA scientists indicate that substantial soil subsidence has occurred since the 1940's. This discrepancy in the topographic model very likely affects the depth targets for NESS. If the NSM topography were altered to have comparable soil subsidence assumptions for WCA-3B north of Tamiami Trail and NESS south of Tamiami Trail, then target depths in NESS would probably be shallower, less water will be needed to meet those targets, and excess depths in WCA-3B would be reduced.

DRAFT CONCEPTUAL MODELS

D-A.1 OVERVIEW OF THE CONCEPTUAL ECOLOGICAL MODELS

This Section describes the role of the Draft Conceptual Ecological Models in the Planning and Evaluation of the South Florida Ecosystem Restoration Program.

D-A.1.1 PREPARERS

John C. Ogden and Steven M. Davis, Senior Ecologists, Executive Office, South Florida Water Management District, West Palm Beach, Florida.

D-A.1.2 INTRODUCTION

The Central and South Florida Restudy and the Southern Everglades Restoration Alliance have adopted the “Applied Science Strategy” as a process for effectively linking science and management during all phases of the planning and evaluation of the south Florida ecosystem restoration programs (SCT 1997, Ogden et al. 1997). The thrust of this strategy is to organize our current, technical understandings of the biology and ecology of natural systems in south Florida into formats that maximize the effectiveness of this information in influencing and supporting policy and management actions. The Applied Science Strategy is a regional and multi-disciplinary process for determining the most appropriate measures of success, and for measuring and evaluating natural system responses resulting from each iteration of the restoration programs. These tasks are prerequisite to the successful application of adaptive assessments during the implementation of the restoration programs. The Applied Science Strategy has been endorsed by the Science Coordination Team of the South Florida Ecosystem Restoration Working Group.

An essential step in the Applied Science Strategy is the creation of a set of conceptual ecological models of the major wetland landscape features in south Florida. These simple, non-quantitative models are an effective means for developing a consensus regarding a set of causal hypotheses, which explain the affects that the major anthropogenic stressors have on the wetland systems. Each model shows the ecological and biological effects of these stressors, the attributes in the natural systems that are the best indicators of the changes which have occurred as a result of the stressors, and the most appropriate measures for each of the attributes. The development of a consensus regarding the components and linkages in the conceptual models is the basis for developing specific hydrological, ecological, and biological performance measures, and for designing a regional, performance-based ecological monitoring program. Conceptual models have been widely used for similar purposes in other regions of North America (e.g., pp. 31-38 in Gentile 1996; also see Rosen et al. 1995).

This report presents the schematic and narrative descriptions for eight conceptual ecological models that are being used by the C&SF Restudy team. The models serve as a basis for developing performance measures and for designing a performance-based monitoring program, for assessing and adaptively managing the south Florida ecosystem restoration program. These eight models are for Lake Okeechobee, the Caloosahatchee and St. Lucie estuaries, the ridge and slough Everglades, the Big Cypress basin, the southern marl prairies, the southern mangrove estuary, Biscayne Bay, and Florida Bay .

D-A.1.3 METHODS

The set of conceptual models were developed and reviewed by over 100 scientists and resource managers who participated in a concentrated program of workshops between October 1996 and August 1997. These workshops were open to all interested participants. Special efforts were made to invite the field scientists in south Florida who have had considerable "hands-on" research experience in these landscapes, and who could bring strong, intuitive perspectives for these systems to the modeling discussions.

The initial steps in the development of each model were to use the informal format of the workshops to identify and discuss the major causal hypotheses relevant to each landscape. From these discussions, the participants created lists of the appropriate stressors, ecological effects, and attributes (endpoints) in each landscape. The objective was to identify the physical and biological components and linkages in each landscape which best characterized the changes explained by the hypotheses. A coordinator for each model used the hypotheses and lists of components to lay out an initial draft of the model, and prepared a supporting narrative document to explain the organization of the model. The drafts and narratives were reviewed in subsequent workshops, resulting in revisions to the models.

D-A.1.4 DISCUSSION

The Applied Science Strategy being used to link science and management in the south Florida ecosystem restoration programs is derived from the "Ecological Risk Assessment" process being used by the U.S. Environmental Protection Agency as a guideline for conducting ecological assessments in North America and Europe (EPA 1992, Gentile 1996). A similar approach was used by the Man and the Biosphere Human Dominated Systems program to define sustainability goals and identify ecological endpoints for a series of restoration scenarios for south Florida (Harwell and Long 1992, Harwell et al. 1996).

Gentile (1996) suggested that risk assessment and recovery of ecological systems "…can be viewed as opposite sides of the same coin." Risk assessment "… is the process of determining the probability (with associated uncertainty) of a particular event occurring as a result of the action of a specific agent or stressor…" Recovery of ecological systems "…can be viewed as the process for determining the probability (with associated uncertainty) of a particular event occurring (e.g., recovery to a…ecologically desired sustainable state) as the result of mitigating the action of a specific agent (e.g., canals, berms) or stressor (e.g., phosphorus). Gentile (1996) listed three principal functions of the risk assessment process: 1) identification of potential causal relationships between stressors and effects; 2) selection of endpoints (attributes), indicators, and success criteria; and 3) development of a scale-dependent conceptual model that describes the inter-relationships between multiple stressor pathways and multiple ecological receptors.

The development and application of conceptual models provides benefits to the scientists who create the models, and to the managers and public who use them to guide and implement resource policy (Gentile 1996, Ogden et al. 1997, SCT 1997). The process of creating and reviewing conceptual models aids scientific endeavors by, 1) creating a forum for open, multi-disciplinary exchanges of ideas and information pertaining to complex ecological issues (i.e., an informal level of peer review); 2) developing scientific consensus regarding current understandings of ecosystems; 3) creating working hypotheses which serve to guide both research and management; 4) better defining and reducing areas of scientific uncertainty; and 5) providing a framework for continuing discussions and revisions as new information becomes available. For managers and the public, the models serve to, 1) de-mystify the science; 2) provide a means for converting broad policy level goals and objectives into specific, measurable targets; 3) provide a visual description of the rationale for the prevailing hypotheses and management priorities; 4) reduce the complexity and dimensionality of the problems; 5) separate essential from non-essential information; 6) provide a tool for improved communication.

Gentile (1996) summarized the importance and appropriateness of the risk assessment and conceptual model process for setting ecological targets and conducting ecological evaluations in regional ecosystem restoration and management programs. The points emphasized by Gentile were, 1) that there is a large body of peer-reviewed literature that describes these methods and processes for conducting ecological assessments; 2) this literature represents an internationally accepted framework for structuring assessments; and 3) considerable effort has been devoted during recent years to formalize the process of selecting and classifying the endpoints, indicators, and metrics used in assessments.

D-A.1.5 CONCEPTUAL MODELS IN THE RESTUDY

The overall Restudy strategy is to use the conceptual models as a basis for developing performance measures and targets for the stressors and attributes in each model. These targets, collectively, describe the physical and biological conditions, respectively, that will be used to define successfully restored natural systems. The rationale for having performance measures and targets for each stressor is that the stressors are known or hypothesized to be the immediate sources of the ecological problems in each landscape. A successful restoration program must remove the adverse affects created by each stressor. A performance measure identifies which elements of each stressor must be corrected, how those elements should be measured, and how those elements must change (i.e., the restoration target) to “neutralize” their adverse effects.

Performance measures are also developed for each attribute in the conceptual models. The attributes have been identified as the biological or ecological elements that are the best indicators of responses in the natural systems to the adverse effects of the stressors. The hypotheses used to construct the conceptual models link each attribute to the stressor(s) which are most responsible for change in that attribute. If the hypotheses are correct, neutralizing the adverse affects of the stressor will result in a predictable positive response by the attribute. The performance measure developed for each attribute identifies the element of that attribute which should respond, how that element should be measured, and how that element should change (i.e., the restoration target) once the affects of the stressor are removed.

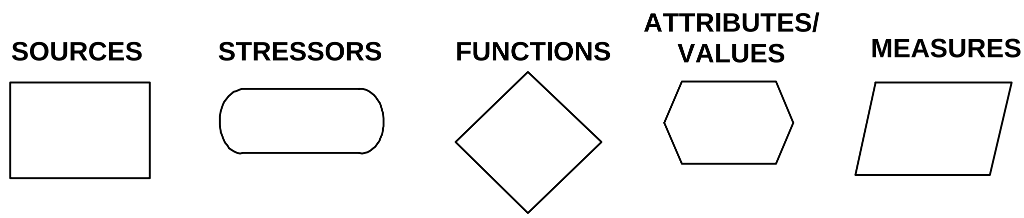
The conceptual model teams have assumed that for the attributes to adequately reveal how the system responds to changes in the stressors, they must reflect responses at a range of temporal and spatial scales, and from different taxonomic and hierarchial levels in ecological systems. They must also be measurable, and their historical patterns, relationships and functions well enough understood, so that responses can be correctly determined and interpreted. The model teams also considered the need for a mix of attributes that can serve either as indicators of ecological conditions or of societal priorities (e.g., endangered species and high quality sports fishing). Finally, the model teams considered the most appropriate number of attributes for each model. The desirable trade-off was to have a sufficient number to adequately reflect the major system responses, while not having more than would be necessary for this purpose or that would contribute to an unmanageably large monitoring program.

The modeling teams also identified critical linkages in the conceptual models. Critical linkages were defined as the links between one or more stressors and attributes, which seemed to explain much of the ecological or biological change in the systems. The assumption was that the stressors that are a part of critical linkages should have a priority over other stressors where restoration programs can not fully negate the adverse affects of all stressors shown in the models. The Restudy alternative evaluation teams generally placed higher priority on meeting performance targets for critical linkage stressors than for other stressors in the models. For example, the ridge and slough conceptual model suggests that stresses caused by reductions in the duration of uninterrupted surface water hydroperiods may explain much of the adverse changes that have occurred in the long-hydroperiod slough systems. Correction of this stressor became the highest priority in evaluating the predicted affects of alternative restoration plans in the central sloughs of the Everglades.

The performance measures and targets from both the stressors and attributes are being used for two primary purposes. The role of the performance measures during the planning phases of the restoration projects is as assessment tools for alternative plans designs. What combination of structural and operational components is most likely to achieve the desired objectives of the project, as determined by how well a plan is predicted (by modeling) to meet each of the targets set by the performance measures? In this planning role, the measures and targets not only are used to measure which plan is most likely to be successful in achieving its objectives, but also are used to influence the design of the project as efforts are made to determine the combination of features which can best moderate or eliminate the adverse affects of the stressors.

The second primary use of the measures and targets is in the design of a system-wide, ecological monitoring program. The purpose of system-wide monitoring is to measure how elements in the natural system actually respond to the management changes brought about following each iteration of a restoration program. Because the design of a restoration program is determined by the features that are predicted to best achieve a suite of regional-scaled performance measure targets, the monitoring program must measure the responses by the same set of measure targets. Comparisons between the predicted responses among stressors and attributes and the actual responses among the same stressors and attributes provide a basis for making revisions to the causal hypotheses and conceptual models, and a means for structuring an adaptive assessment strategy throughout the implementation of the restoration program. The overall focus of the monitoring program must be performance-based, i.e., the elements of the natural systems to be monitored must be those that provide actual measures of the stressor and attribute targets.

A figure of the conceptual models is included with the narrative for each model. The conceptual models follow a top - to - bottom hierarchy of anthropogenic and natural drivers, their respective stressors, the ecological effects resulting from the stressors, and ecological attributes/values and measures. Each attribute is linked to one or more stressor. The measure for each attribute is a priority component for a comprehensive monitoring program. The symbols used in the figures are:



D-A.1.6 ADAPTIVE ASSESSMENT

The key to successful implementation of a regional ecosystem restoration program, e.g., maximizing the effectiveness of the program and reducing uncertainty during its implementation, is an adaptive assessment strategy. The conceptual ecological models are an integral part of the overall adaptive assessment strategy. The conceptual models are revised based on interpretations of actual system responses following the implementation of each restoration project. These revisions in the conceptual models influence predictions of system responses for future iterations during the implementation process. As the accuracy of the hypotheses and conceptual model linkages improve, the opportunities for making pre-construction improvements in project design are also enhanced. Greater accuracy in the conceptual models leads to improvements in the choice of measures and targets used to judge the predicted performance of each project design.

D-A.1.7 FUTURE TASKS

The conceptual ecological models, and the planning and evaluation tools coming from the models, still require several priority improvements. These are: 1) completion of a conceptual model technical report, and peer review of this report; 2) a new series of workshops to complete the development of performance measures for the biological attributes identified by the models; 3) workshops to design a performance-based monitoring program for the south Florida ecosystem restoration program; and 4) the development of a consensus among the participating agencies for a system-wide adaptive assessment strategy for the ecosystem restoration program.

D-A.2.2 INTRODUCTION

Lake Okeechobee is a large (1,730 km^2) freshwater lake located at the center of the interconnected south Florida aquatic ecosystem. The lake is shallow (average depth <3 m), originated about 6,000 years ago during oceanic recession, and under natural conditions probably was a slightly eutrophic and had vast marshes to the west and south. The southern marsh was contiguous with the Florida Everglades, which received water as a broad sheet flow from the lake during periods of high rainfall (Gleason 1984).

Modern-day Lake Okeechobee differs in size, range of water depths, and connections with other parts of the regional ecosystem (Havens et al. 1996a). Construction of the Herbert Hoover Dike in the early to mid-1900s reduced the size of the lake's open-water zone by nearly 30%, resulted in a considerable reduction in average water levels, and produced a new littoral zone within the dike that is only a fraction of size of the natural one (yet still it is a vast expanse, at over 400 km^2). The lake also has been impacted in recent decades by excessive inputs of nutrients from agricultural activities in the watershed (Flaig and Havens 1995). These nutrients have exerted the most dramatic impacts on the open-water region, where large algal blooms have occurred, along with accumulation of soft organic mud bottom sediments, which cause the lake water to become highly turbid when they are resuspended during windy periods (Maceina and Soballe 1991). The littoral zone has been invaded by 15 species of exotic plants, most notably *Melaleuca quinquenervia* and *Panicum repens* (torpedo grass), which have expanded over large areas, displacing native plants. Despite these human impacts, and a consensus that the lake's overall health has been greatly degraded by human actions, Lake Okeechobee continues to be a vital aquatic resource of south Florida, with irreplaceable natural and societal values. These values and their responses to anthropogenic stressors are described in the following sections.

D-A.2.3 MODEL STRUCTURE

The conceptual model is comprised of a top-to-bottom hierarchy of **sources**, **stressors**, **ecosystem effects**, **values**, and **measures** (refer to figure on page D-A-21). It is a complex model that includes two distinct but highly interconnected components, the open-water and littoral zones; each zone has different ecological effects and endpoints, and different responses to stressors. Stressors in one zone may have indirect effects that cross the boundary into the other. The Lake Okeechobee model was developed in the context of the lake's existing spatial extent, recognizing that the functioning of the modern-day system is drastically different from that of the historic lake.

D-A.2.4 STRESSORS AND EXTERNAL SOURCES

Eight in-lake stressors, which exert significant impacts on the lake's natural and societal values, originate from six external sources. Elevated concentrations of **chemical contaminants**, including, chloride (Cl^-), pesticides, and total dissolved solids (TDS), are by-products of agriculture or other human activities in the watershed. A much greater concern, in terms of ecosystem impacts, are the massive quantities of **nutrients**, in particular nitrogen (N) and phosphorus (P), which are discharged to the lake from agriculture. The C&SF Project, which includes deep canals that allow water to enter the lake with little interaction with natural wetlands, facilitates the delivery of these chemical stressors to Lake Okeechobee, and as such, it also is considered a source.

The open-water region experiences elevated concentrations of **suspended sediments**, whose source is a region of soft organic mud that covers about 50% of the lake bottom. When winds mix the shallow water column, the upper few cm of mud are resuspended. The spatial extent, depth, and nutrient content of this mud have increased rapidly in the last 100 years, coincident with agricultural development and increased nutrient inputs from the watershed (Brezonik and Engstrom, 1997). The Herbert Hoover Dike may facilitate sediment accumulation by preventing natural flushing that once may have occurred during high water events.

The C&SF Project, along with natural variations in regional rainfall, have the potential to cause **prolonged or extreme high or low water levels**. Because the lake is constrained within the dike system, these two stressors can cause severe damage on the lake ecosystem. Extreme high or low lake levels of <u>any</u> duration, or moderate high or low lake levels of <u>prolonged</u> duration, are considered to cause significant harm (an adverse change in ecological values that cannot recover under natural conditions). In contrast to the harmful effects of extremes, a certain degree of natural variation in lake levels, between 13 and 15 ft NGVD, has been shown to be benefit the ecosystem (Smith et al. 1995; Smith 1997).

Lake Okeechobee has suffered in recent decades from the expansion of **exotic and nuisance plants** and **exotic animals**. Today there 15 species of exotic plants in the littoral zone. Species of greatest concern are *Melaleuca* and torpedo grass, both of which were purposely introduced to the region, for dike stabilization and cattle forage, respectively. Other exotic plants that have stressed the lake's values include *Hydrilla* sp., water hyacinth (*Eichhornia crassipes*), and water lettuce (*Pistia stratiotes*). Exotic animals in the lake now include fish (*Tilapia aurea),* mollusks (*Corbicula fluminea*), and microinvertebrates (*Daphnia lumholtzii*). Each of these species exerts different impacts on the ecosystem, as discussed below. The final major stressor in Lake Okeechobee is **increased frequency and extent of fire**, which occurs due to natural causes (e.g., lightening strikes), arson, and controlled burns conducted by the South Florida Water Management District and Florida Game and Fresh Water Fish Commission, under permit from the US Department of Forestry.

D-A.2.5 ECOLOGICAL VALUES / ATTRIBUTES

Seven natural and societal values are associated with the Lake Okeechobee ecosystem. These values may be broken down into those which are <u>intrinsic</u> to the lake (fisheries, wildlife habitat, ecotourism) and those which are <u>extrinsic</u> (water supplies for urban areas, agriculture, and other ecosystems). The extrinsic values differ in that they are regional in nature, and dependant upon water supply in general, rather than on Lake Okeechobee per se. It is largely for this reason that lake hydrologic performance measures (below) are based on the lake’s intrinsic values, while extrinsic values are addressed separately, by performance measures ascribed to the Lake Okeechobee Service Area. Nevertheless, the conceptual model can serve as an integrating framework for these different values.

The lake is an important source of **water for urban and agricultural uses,** and **environmental water** that is discharged from the lake to other ecosystems, including the east and west coast estuaries, and the Everglades water conservation areas. For each of these extrinsic values, the quantity, timing, and quality of water are critical features. The lake is important to the regional economy, whose income depends in part on use of the ecosystem for **ecotourism and recreation**, including bird and wildlife observation, hiking, camping, and recreational boating. The lake also supports a **commercial and recreational fishery**, with an estimated "total economic value" in excess of $480 million US dollars (Furse and Fox 1994). Some of the most important intrinsic ecological values of the lake are the **wading birds and waterfowl**, which include numerous species and large resident or migratory populations (Smith et al. 1995), and the **diverse mosaic of native vegetation** that characterizes the lake's littoral marsh zone (Richardson and Harris 1995). This diverse vegetation is critical to birds, fish, and other wildlife that inhabit the zone, and it is an aesthetically pleasing region that is visited by thousands of persons each year -- thereby supporting the ecotourism, recreation, and fisheries values mentioned above. The community also is a critical habitat for the federally-endangered **snail kite**, whose principal food resource, the apple snail, occurs at high densities in a large pristine region of the lake's marsh known locally as Moonshine Bay.

D-A.2.6 QUANTITATIVE MEASURES

To quantify the current status of Lake Okeechobee, and its predicted or realized responses to restoration efforts, a suite of measures were selected that collectively characterize the condition of each ecological value. Measures were based on the results of scientific research, or in some cases, best professional judgement that indicates a strong relationship between measures and the values being assessed. The measures for Lake Okeechobee ecological values are as follows.

(1) Urban water quality and quantity. Key measures of the quality of water for urban uses include concentrations of the various Class I numeric water quality standards (for drinking water use), as well the concentrations of Class IV numeric standards (for agriculture). Water quantity can be assessed as days per year with water use restrictions.

(2) Environmental water quality and quantity. Water discharged from Lake Okeechobee may impact downstream ecosystems, including the east and west coast estuaries, the WCAs, and the Everglades, if it contains high concentrations of P, N, toxins, or turbidity. Quantities of water depend on needs of particular ecosystems, and must include a seasonal component.

(3) Ecotourism and recreation. These ecological values may be best assessed on the basis of numbers of visitors to the lake region each year and cash flow into the local economy, associated with designated lake uses, including bird and wildlife observation, hunting, boating, and hiking.

(4) Sport and commercial fishery. Measures of fishing success may be obtained from information on catch per unit effort by anglers and commercial fishers, while more quantitative information can be obtained by FGFWFC studies of population size and age structure for selected fish (largemouth bass, black crappie, bluegill).

(5) Wading birds and migratory waterfowl. Populations of selected birds may be surveyed in order to determine population sizes and nesting success.

(6) Diverse mosaic of native vegetation. Geographic Information System (GIS) maps of the littoral zone may be used to evaluate indices of overall spatial heterogeneity - several standard ones are available. It also may be important to quantify changes over time the spatial extent of selected vegetation assemblages, especially those known to be critical wildlife habitats (e.g., *Eleocharis, Scirpus, Salix*). The ratio of exotic+nuisance to native plant coverage also may be a useful metric of overall vegetation quality. The marsh community is reported to include one threatened

plant species, the Okeechobee gourd, and a regular census of its population density and distribution should be undertaken.

(7) Snail kite. Snail kites are an important endangered species in south Florida, and there needs to be a continued regular census of their population size and nesting success in Lake Okeechobee.

D-A.2.7 ECOSYSTEM EFFECTS

The pathways linking ecosystem stressors to the natural and societal values are complex, and have a solid foundation in research and modeling conducted by scientists at the SFWMD, FGFWFC, and Florida universities (e.g., Aumen and Wetzel 1995, Havens et al. 1995, James and Bierman 1995, Reddy et al. 1995, Havens et al. 1996a). As we learn more about how the system functions, it is likely that additional pathways could be added to the model, or adjustments made to existing pathways. The model is a flexible tool that at any given time, reflects the current state of our best available scientific information.

Chemical contaminants in the lake water have the potential to directly impact all seven of the ecological values. Toxic materials in drinking water are dangerous to human users, or at a minimum, costly to remove during treatment operations; toxic chemicals also can kill or harm agricultural crops and the biota residing in downstream ecosystems that receive environmental water deliveries or flood control discharges from the lake. Toxic chemicals also may kill or harm native invertebrates, fish, birds, littoral plants, and other flora and fauna in the lake ecosystem, including the endangered species. Some of the chemical contaminants, including Hg and pesticides, undergo biomagnification in the food web, and thereby indirectly harm animals near the top of the web (e.g., predator birds, fishes, and other animals such as the American alligator).

Nutrients, in particular N and P, stimulate the growth of phytoplankton, and at the extreme, can cause noxious surface blooms of blue-green algae (Paerl 1988). When these algal blooms senesce, they can cause oxygen depletion and a build-up of ammonia and potentially toxic decay products in the water. Depending on the location where this occurs, these decay products can harm components of the lake's biota, including littoral macroinvertebrates and fish. This in turn can secondarily affect the predators that utilize those food resources. To date, the only documented harm, following a large bloom in summer 1986, was to the lake's apple snail population (Jones 1987), the primary food item for the endangered snail kite. The products of algal bloom decay also are detrimental to water quality for urban and environmental deliveries, and to the ecotourism & recreational uses of a lake (Heiskary and Walker 1988). The high nutrient inputs that have impacted Lake Okeechobee since human development began pre-1900 also have left their mark on the lake sediments (Reddy et al. 1995), which now contain large quantities of N and especially P. While there is a natural loss of N from the lake, by microbial degradation in a process called denitrification, there is no such loss for P, except by gradual burial in deeper sediment layers. High concentrations of P and organic material promote rapid growth of bacteria, which in turn deplete the oxygen from surface sediments (Hutchinson 1957). Only a small subset of benthic macroinvertebrates can tolerate low oxygen levels, and it is for this reason that the Lake Okeechobee community, once dominated by a diverse array of species, now is strongly dominated by a few species of pollution-tolerant oligochaete worms (Warren et al. 1995). This change radiates upward through the food web, affecting fishes and other animals that ultimately depend on the benthic invertebrates as a food source (Havens et al. 1996b).

Suspended sediments in the water column can cause increased P concentrations if soluble P is released from the sediment particles. This is a complex situation that is largely controlled by the concentrations of P on the particles and in the water column (Reddy et al. 1995). Under most circumstances, the particles adsorb P, and therefore sediment suspension (followed by sediment settling to the lake bottom) is a net sink for P. Suspended sediments exert another important impact. If they are present in the water column at high concentrations, they greatly reduce the amount of light that reaches the lake bottom. It the sediments are circulated to shallow near-littoral regions of the lake (this circulation appears to be enhanced by high water levels), then they may suppress the growth of submerged plants and algae that naturally occur on the lake bottom. Those plants and algae are important because they provide food and habitat for macroinvertebrates and fish (and ultimately wading birds and other animals), and they help to stabilize the sediments. If the plants are reduced or eliminated, these functions are lost. One particularly troubling result is a "positive feedback loop" that may occur, making it very difficult for the lake to recover from a highly turbid condition: turbid water reduces benthic plants, less benthic plants means more resuspension, this makes more turbid water, even less plants........etc. This situation may be occurring today at the south end of Lake Okeechobee, where turbid, P-rich water and declines in benthic algae (*Chara*) coincided with the prolonged high lake stages in 1995 and 1996 (Steinman et al. 1997). Research results also have documented that benthic algae compete for nutrients with phytoplankton (Havens et al. 1996c). Thus, when benthic algae are reduced, there is a greater potential for phytoplankton blooms. Finally, there also is a complex relationship between light penetration in the water column and phytoplankton biomass. While sediment resuspension may indirectly promote phytoplankton growth by suppressing benthic algae, at the extreme, it may be so severe as to cause light limitation of the phytoplankton too. In this case, which is typical of the mid-lake region during winter (Phlips et al. 1997), there may be little growth of any algae in the water column or on the lake bottom. At other times, when a high biomass of phytoplankton does occur (e.g., during calm mid-summer periods), phytoplankton cells may bring about a reduction in light penetration, and also contribute to the decline in benthic algae.

Prolonged or extreme high lake levels cause substantial harm to the ecosystem. When sustained high lake levels (>15 ft for nearly 2 yrs, and exceeding 17 ft at the extreme) occurred in 1995 and 1996, wind and erosion caused emergent plants to be torn loose from their habitats, resulting in a loss of important fish and wildlife habitat (e.g., bulrush, a critical spawning habitat for largemouth bass). These "islands" of dislodged plant material also interfered with recreational uses of the lake, as they blocked canals and boat trails. During the two years of high lake levels, District scientists also documented the loss of submerged vegetation at the lake's south end, likely due to light limitation caused by the deep, turbid water (Steinman et al. 1997).

High lake levels also bring about changes in the nature and extent of mixing within the lake. A Lake Okeechobee hydrodynamic model indicates that when water levels are high, nutrient and sediment-rich water from mid-lake is mixed throughout the basin, including into the littoral zone (Sheng and Lee 1991). At low water levels, the nutrient and sediment-rich water circulation is constrained towards mid-lake because an extensive rock reef along with south and west edges of the open-water region restricts water movement into the near-littoral region (Maceina 1993). When high water levels promote nutrient transport into the marsh *via* greater horizontal mixing, those nutrients have the potential to cause changes in the biomass and composition of both marsh plants and algae, as has been documented in the Everglades Water Conservation Areas (WCA) by Koch and Reddy (1992) and McCormick et al. (1996).

High lake levels also may affect vertical mixing in the mid-lake region. During summer calm periods, the water column may become thermally stratified for one to two week-long periods (Jin et al. 1997). When this occurs, bottom waters may become anoxic, and this in turn allows diffusion of soluble P from lake sediments. These events may be a precursor to development of mid-lake blooms of blue-green algae (Havens et al. 1997). Because it takes a greater amount of wind energy to break down the stratification and mix a deeper water column than a shallow one, high lake levels might promote longer-lasting mid-summer stratification, anoxia, and algal blooms (Havens 1996). High lake levels also may threaten the endangered Okeechobee gourd, which cannot tolerate prolonged flooding.

Prolonged or extreme low lake levels also cause significant harm to the ecosystem and its values. Low water levels expose large areas of the marsh (including native plant communities such as *Scirpus* and *Eleocharis*) to desiccation, and render them useless as habitats for fish and waterfowl. Low water levels also may promote the expansion of exotic plants. The large *Eleocharis* habitat found in Moonshine Bay is an important habitat because it is a primary foraging area for largemouth bass and other recreational fish, and it supports a thriving population of snail kites. This habitat now is encircled by torpedo grass, which may readily overtake the region if low water levels suppress the growth and survival of the native *Eleocharis*. Torpedo grass grows most rapidly when water levels are at or near the soil surface, and displays considerable growth suppression when submerged under >30 cm of water (Thayer and Haller 1990). *Eleocharis,* on the other hand, thrives when submersed, even when water depths are near 1 m. There also is evidence that germination of Melaleuca seeds is inhibited by standing water (Lockhart 1995). Hence, if large areas of the marsh become dry for long periods of time, there could be increased expansion of this exotic plant. Indeed, one of the most rapid *Melaleuca* increases occurred shortly after the 1990 drought, when lake levels declined below 11 ft NGVD for just 150 days. Low lake levels also impact ecotourism and recreation, by making it difficult or impossible to access large regions of the marsh (many former boat trails become dry land at 11 ft NGVD). Finally, there is evidence that low water levels directly impact the snail kite, which requires standing water beneath the macrophytes upon which it constructs its nest.

While it is clearly the case that prolonged or extreme high and low water levels have negative impacts, these attributes alone do not describe the hydrologic variation that is required to maintain a healthy ecosystem. There is considerable evidence that the "optimal" situation would also include a certain degree of variation. In particular, a January to May recession in lake levels from near 15 ft NGVD to below 13 ft NGVD has been shown to be beneficial to wading bird and fish populations. Infrequent (every 5 to 7 years) spring recessions to below 12 ft NGVD may benefit the entire community, by exposing prey-rich submersed macrophyte beds to predators, invigorating willow (*Salix*) stands, and by allowing fires to burn away *Panicum* and *Typha* wrack (Smith et al. 1995). These points must be taken into account when evaluating the impacts of regional restoration programs or lake regulation schedules, although they are not readily portrayed as stressors in a conceptual model of this format.

Exotic and nuisance plants have been discussed in the context of water levels and other stressors. These plants, which now cover a large portion of the marsh, exert a variety of direct and indirect impacts on the lake's ecological values. As they spread and displace native vegetation, they directly alter the vegetation mosaic. Because of their growth characteristics, they may provide poor habitat for fish and other wildlife. Torpedo grass, for example, grows in large monocultures resembling “hayfields,” with little or no standing water. Fish simply cannot swim through such a habitat, and any wildlife that depend upon those fish as a food resource are indirectly affected when torpedo grass becomes dominant in a region of the lake. *Hydrilla* and other exotic submerged plants have negative impacts on human uses of the system, by blocking canals and waterways, and often requiring repeated herbicide treatments. These plants are secondarily responsible for any adverse impacts that the herbicides have on natural vegetation in the lake or downstream ecosystems. One of the troubling patterns observed in the lake's marsh is expansion of cattail (*Typha*). This plant is a native, but once occurred at considerably lower densities and over a smaller spatial area (Richardson and Harris 1995). Its spread may be related to water level regimes and/or eutrophication of the lake. In either case, it displaces other native plants and impacts the value of the marsh as a wildlife habitat. There is some concern that cattail expansion in to valuable bulrush habitat may be facilitated by low lake levels (particularly those < 11 ft NGVD). Following the drought in 1989, when the lake declined to nearly 10.5 ft NGVD, large areas of bulrush became infested. These events may degrade the value of the habitat for fish and other wildlife that utilize bulrush for nesting or foraging.

Exotic animals in Lake Okeechobee can directly displace native animals through competition and predation, and they also can exert other direct and indirect effects. *Tilapia aurea*, for example, is an exotic fish that feeds and burrows at the benthos, and destroys submerged vegetation stands. It also transforms particulate nutrients, from sediments, macroinvertebrates, and plants, into soluble nutrients that are excreted into the water column where they may stimulate localized algal blooms. Not all impacts of exotic animals are negative, however. The mollusk *Corbicula fluminea* is a major food source for diving ducks and shell crackers, and the microinvertebrate *Daphnia lumholtzii* grazes phytoplankton, and could suppress algal blooms if its densities become very high. It also may be a good food source for plankton-feeding forage fish.

Fire is a natural forcing function in Lake Okeechobee, as well as in other south Florida ecosystems, often occurring due to natural causes, such as lightening strikes. However, in recent years, fires have been set in the lake's littoral zone by humans -- both in acts of arson, and as part of controlled burn management efforts. Arson fires are reportedly set by hunters and others who desire to visit the littoral zone for recreational purposes. The focus is most often on regions of dense torpedo grass, where plant growth has restricted access to the marsh. Interestingly, the controlled burn programs target similar regions, but for a different reason -- to burn away the exotic plant material, in order to give native plants a chance to recolonize the area from a rich buried seed bank that is known to occur in the marsh soil. In either case, fires impact the vegetation mosaic, as well as the animals that occur therein.

D-A.2.8 HYDROLOGIC PERFORMANCE MEASURES

A significant feature of the Lake Okeechobee conceptual model is the high degree of interconnectedness; any given stressor may impact ecological values directly, or impact those same values indirectly, by exacerbating the effects of other stressors. Two stressors that display particularly strong effects (direct and indirect) on the values are high and low water levels. Taken together, they have the potential to affect the rate of lake eutrophication, the spatial extent and overall health of submerged and emergent plant communities, fisheries, birds, other wildlife, and the quality of water taken from the lake from human uses.

Water inputs and lake levels also are the variables most directly impacted by the various Alternatives considered in the C&SF Restudy. Therefore, a suite of hydrologic performance measures were developed based on water depth (and seasonal variations in those depths). These measures serve as integrative predictors of overall lake ecosystem health.

The hydrologic performance indicators and measures for Lake Okeechobee are concerned with: extreme high lake levels (> 17 ft NGVD) of any duration; moderate high lake levels (> 15 ft NGVD) of prolonged duration; extreme low lake levels (< 11 ft NGVD) of any duration; and moderate low lake levels (< 12 ft NGVD) of prolonged duration; as well as the degree of variability in lake levels, within what is considered to be an "optimal" window for the lake's biota (13 to 15 ft NGVD).

D-A.2.8.1 Performance Indicator – Daily Stage Hydrographs

Visual inspection of daily stage hydrographs, for the period from January 1965 to 1995, can provide information regarding the frequency of extreme high and low lake levels. One simply draws horizontal lines across these plots at 17 ft and 11 ft NGVD water levels, and counts the number of cases wherein the hydrograph goes above or below the lines. The fewer the events, the "better" the result, in terms of protecting the lake's values. The restoration goal for the lake is to have no such events.

D-A.2.8.2 Performance Indicator – Stage Duration Curves

Visual inspection of stage duration curves for various alternatives and base conditions can provide additional information that is directly related to the lake's values. By drawing horizontal lines across the plot at 17 ft and 11 ft NGVD, one can quantify the percent of times that lake stage exceeded or fell below these critical values. Lower percentages in a given scenario equate to a "better" result. The restoration goal for the lake is to have zero % for each extreme type of event.

D-A.2.8.3 Performance Measure – Similarity in Duration of Stage Events > 15 ft

This performance measure consists of box and whisker plots, which indicate median, maximum, minimum, and 25^{th} / 75^{th} percentiles, for duration of moderate high lake stage events. As indicated above, prolonged lake levels above 15 ft NGVD cause significant harm to the lake's ecological values, and should be avoided. For this measure, lower median values and extremes are better. The restoration goal for the lake is to have a median duration near zero, and a maximal duration no greater than 1 year.

D-A.2.8.4 Performance Measure – Similarity in Duration of Stage Events < 12 ft

This performance measure is analogous to the preceding one, except that it is concerned with the duration of moderate low lake levels. Lower median and extreme values are better. The restoration goal for the lake is to have a median duration near zero, and a maximal duration no greater than 1 year.

D-A.2.8.5 Performance Measure – Similarity in Duration of Stage Events > 11 ft

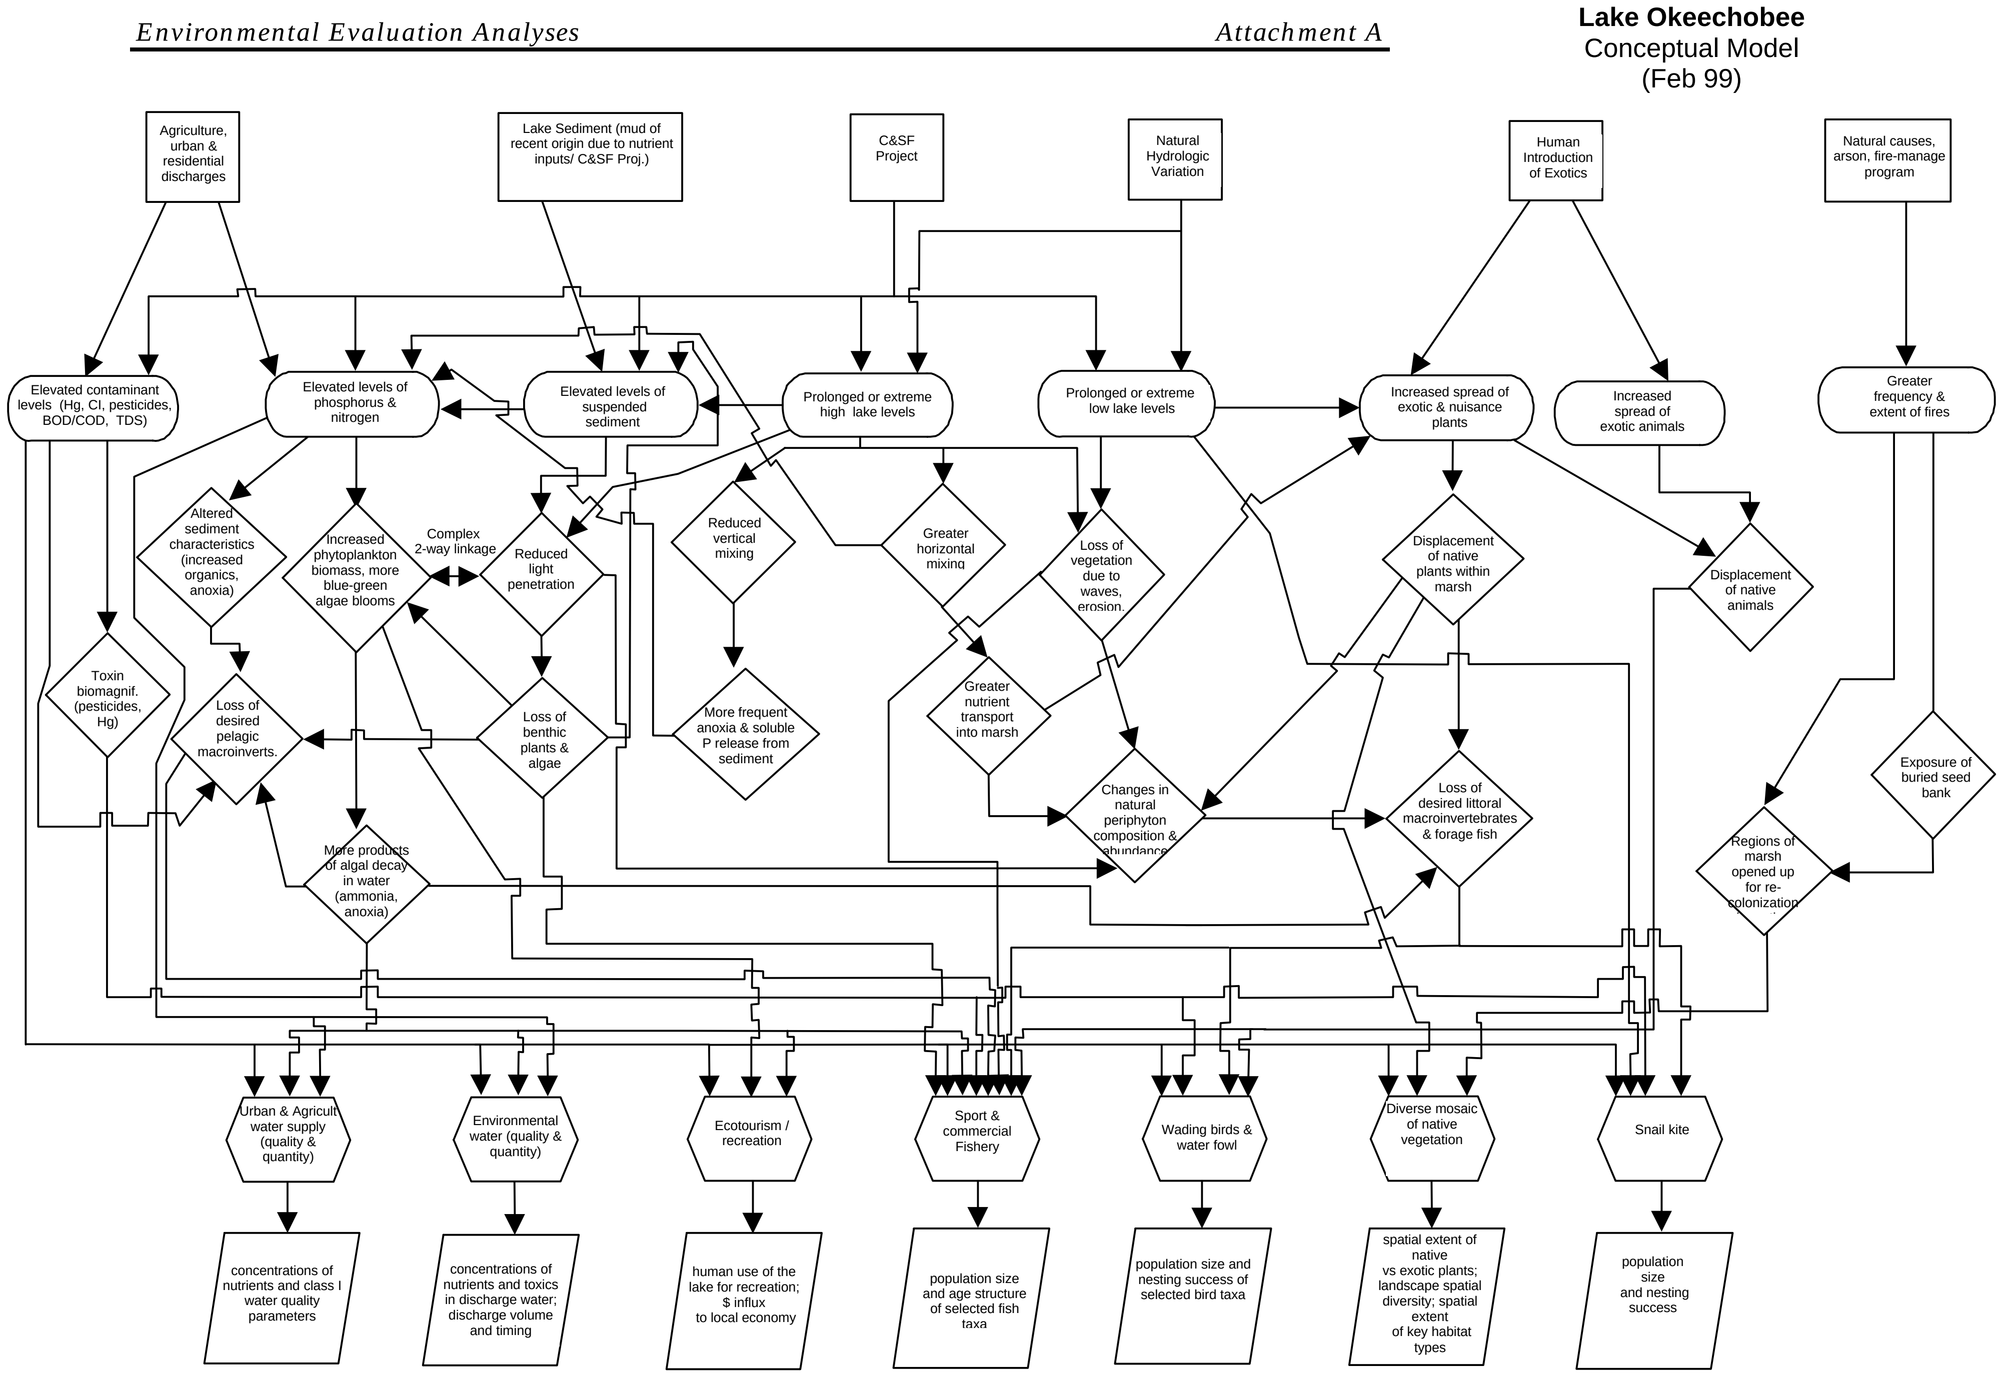
When lake stage falls below 11 ft NGVD, significant harm ensues, even if the duration is short. Nevertheless, during regional droughts, lake levels have declined to as low as 9.6 ft NGVD. Alternatives that increase the duration of < 11 ft events are considered especially harmful to the ecosystem. This performance measure uses box and whisker plots, as in the previous item. Lower medians and extremes are better. The restoration goal for the lake is to have no such events (i.e., duration median and extreme = zero).

D-A.2.8.6 Performance Measure – Similarity in Duration of Stage Events > 17 ft

This performance measure is analogous to the preceeding one, except that it is concerned with the duration of extreme high lake levels. Lower median and extreme values are better. The restoration goal for the lake is to have no such events (i.e., duration median and extreme = zero).

D-A.2.8.7 Performance Measure – Daily Stage Hydrographs with Spring Recession Windows

In an effort to evaluate the degree to which intra-year variations in lake levels match the optimal pattern described by Smith et al. (1995), that is, a January to May recession, without reversal, from near 15 ft to below 13 ft NGVD, “windows” were drawn over the daily hydrograph plots. Years in which the lake levels recede smoothly from the upper left to lower right corners of the box are considered “good” for wading birds and other wildlife in the lake. Years in which lake levels remain far above or below the box, or those with water levels passing through the box with no trend or an increasing trend in lake levels are considered “bad.” A greater number of years with “good” scores is considered a better result. More elaborate methods may be utilized to score the results, however, it is unclear whether this is called for, given existing uncertainties about the true relationship between spring lake level recession and fish / wildlife health. Furthermore, it is uncertain whether the goal for this measure is to have the designated recession every year, or at a return frequency corresponding to some selected reference period.



Lake Okeechobee
Conceptual Model
(Feb 99)
Agriculture, urban & residential discharges
Lake Sediment (mud of recent origin due to nutrient inputs/ C&SF Proj.)
C&SF Project
Natural Hydrologic Variation
Human Introduction of Exotics
Natural causes, arson, fire-manage program
Elevated contaminant levels (Hg, Cl, pesticides, BOD/COD, TDS)
Elevated levels of phosphorus & nitrogen
Elevated levels of suspended sediment
Prolonged or extreme high lake levels
Prolonged or extreme low lake levels
Increased spread of exotic & nuisance plants
Increased spread of exotic animals
Greater frequency & extent of fires
Altered sediment characteristics (increased organics, anoxia)
Increased phytoplankton biomass, more blue-green algae blooms
Complex 2-way linkage
Reduced light penetration
Reduced vertical mixing
Greater horizontal mixing
Loss of vegetation due to waves, erosion
Displacement of native plants within marsh
Displacement of native animals
Toxin biomagnif. (pesticides, Hg)
Loss of desired pelagic macroinverts.
Loss of benthic plants & algae
More frequent anoxia & soluble P release from sediment
Greater nutrient transport into marsh
Changes in natural periphyton composition & abundance
Loss of desired littoral macroinvertebrates & forage fish
Exposure of buried seed bank
Regions of marsh opened up for re-colonization
More products of algal decay in water (ammonia, anoxia)
Urban & Agricult water supply (quality & quantity)
Environmental water (quality & quantity)
Ecotourism / recreation
Sport & commercial Fishery
Wading birds & water fowl
Diverse mosaic of native vegetation
Snail kite
concentrations of nutrients and class I water quality parameters
concentrations of nutrients and toxics in discharge water; discharge volume and timing
human use of the lake for recreation; $ influx to local economy
population size and age structure of selected fish taxa
population size and nesting success of selected bird taxa
spatial extent of native vs exotic plants; landscape spatial diversity; spatial extent of key habitat types
population size and nesting success

D-A.3 DRAFT ST. LUCIE AND CALOOSAHATCHEE CONCEPTUAL MODEL

D-A.3.1 PREPARERS

Susan Gray and Daniel E. Haunert, South Florida Water Management District, West Palm Beach, Florida.

D-A.3.1.1 Contributors

The following persons contributed to the development of the estuary conceptual model: Robert Day (Indian River Lagoon NEP); Tom Fraiser (W. Dexter Bender & Assoc.); Ernie Estevez (Mote Marine Lab); Keith Kibby (Lee County); Doug Strom (FDEP); Greg Graves (FDEP); Herb Zebuth (FDEP); Kalani Cairns (USFWS); Robert Pace (USFWS); Steve Traxler (USACE); Dennis Hanisak (Harbor Branch Oceanographic Institute); Tony Janicki (Coastal Environmental); Ralph Montgomery (Coastal Environmental); Patti Sime (SFWMD); Bob Chamberlain (SFWMD); Peter Doering (SFWMD); David Rudnick (SFWMD); Chris Madden (SFWMD); Steve Davis (SFWMD); Barry Rosen (SFWMD); Joel Van Arman (SFWMD)

D-A.3.2 ABSTRACT

A conceptual model of the St. Lucie and Caloosahatchee Estuaries was developed by scientists working in these systems to identify major stressors, measurable attributes of the ecosystem that are sensitive to the stressors, and linkages between the two. Both estuaries have been highly modified. The St. Lucie Estuary, located on the southeast coast of Florida, discharges into the Indian River Lagoon and Atlantic Ocean through the St. Lucie Inlet. The Caloosahatchee Estuary, located on the southwest coast of Florida, discharges into Charlotte Harbor, and then into the Gulf of Mexico. Due to extensive urban and/or agricultural drainage projects in both watersheds, the historic watershed area has been greatly expanded. In addition, both estuaries are linked to Lake Okeechobee via canals that provide both navigation and releases of floodwaters. In the Caloosahatchee, the construction of a water control structure downstream of Lake Okeechobee has also decreased the tidally influenced portion of the Caloosahatchee Estuary. The major effects of anthropogenic changes in both watersheds are significant alterations in the timing, distribution, quality, and volume of freshwater entering the estuaries. Understanding how these systems respond to stress will provide a basis for well-informed management decisions on restoration activities.

D-A.3.3 INTRODUCTION

The St. Lucie Estuary is located on the southeast coast of Florida, and discharges into the Indian River Lagoon and Atlantic Ocean at the St. Lucie Inlet. The estuary encompasses about eight square miles, and the historic watershed was estimated to be about 1/3 the size of its present configuration. Due to extensive agricultural and urban drainage projects beginning in the 1910s, the present day watershed area has been expanded to almost 775 square miles. Major canals in the watershed include the C-23 and C-24 canals, part of the Central and South Florida Flood Control Project. In addition, the estuary is linked to Lake Okeechobee by the C-44 canal that is utilized for both navigation and the release of floodwaters from the lake.

The Caloosahatchee Estuary is located on the southwest coast of Florida, and discharges into Charlotte Harbor, and then into the Gulf of Mexico. The Caloosahatchee Estuary is also connected to Lake Okeechobee through the C-43 canal (Caloosahatchee River), and there are a series of smaller drainage works in association with substantial agricultural development in the watershed. The construction of a water control structure (Franklin Lock and Dam) downstream of Lake Okeechobee has decreased the tidally influenced portion of the estuary, allowing for the convenient use of the C-43 as a potable water supply.

The major effects of anthropogenic changes in both watersheds are significant alterations in the timing (excess wet season flows, insufficient dry season flows), distribution, quality, and volume of freshwater entering the estuaries. In addition, alterations within the estuaries through dredging of navigation channels, filling of marshes, and construction of bridges and causeways has also contributed to a number of documented declines in some mollusc species and submerged aquatic vegetation. Restoration of these important species is considered critical to the overall health of these systems. Despite these impacts, the estuaries continue to be an important resource, with significant environmental and economic values.

D-A.3.4 ESTUARY MODEL STRUCTURE

The conceptual model for the St. Lucie and Caloosahatchee Estuaries follows the format used for other south Florida ecosystem models, with a top-to-bottom hierarchy of **sources**, **stressors**, **ecosystem effects**, **attributes** and **measures**. Refer to figure on page D-A-30. The model is similar to those developed for other ecosystems, including Florida Bay and Lake Okeechobee. One significant difference is that a single model diagram is proposed for both estuaries. During the development of this model, it became apparent that one design would serve both systems, but that the emphasis or relative importance of each segment could vary between the systems.

D-A.3.5 ECOLOGICAL & SOCIETAL VALUES / ATTRIBUTES

Nine ecological and societal values associated with a healthy estuarine ecosystem were identified, along with measures that will provide information on current ecological status, as well as long-term trends. These include the following:

- **Mollusc abundance & distribution –** Oysters, clams and scallops are natural components of southern estuaries, and have been documented in the past to be abundant in these systems. Oyster reefs provide several important functions, including habitat and food for other species. Scallops, clams and oysters may be a commercial and/or recreational resource.

- **Sediment quality** directly affects the occurrence and abundance of benthic and sessile species. Sediments are a sink for nutrients and other materials, such as pesticides and metals.

- **Water quality** is a major determinate of the health and condition of aquatic systems, and changes in water quality are often the linkage between the stressor and the ecosystem value.

- **Submerged aquatic vegetation (SAV) distribution and abundance -** Seagrasses are considered to be a key feature of estuaries due to the functions that they perform. These functions include sediment stabilization, primary productivity, and nursery and refugia habitat.

- **Habitat structure and function**, as considered on a landscape scale, integrates many of the other values. An example of a landscape-scale attribute is defining a preferred salinity regime for the estuary. Work on the St. Lucie and Caloosahatchee Estuaries has identified preliminary salinity ranges and seasonal and spatial distributions, termed “salinity envelopes” to meet the physiological requirements for the establishment and productivity of key estuarine species, including seagrasses and oysters.

- **Benthic invertebrate community structure -** The composition of invertebrate species in the benthos serves as an indicator of the nutrient and contaminant loading to the system. Changes in species diversity and abundance have been documented in the presence of increased pollutant loadings.

- **Manatee population dynamics -** Manatees are a very visible and popular feature of the estuary, and impacted by changes to the ecosystem. Their status as an endangered species adds considerable importance to their protection and stabilization of their populations.

- **Fisheries population dynamics -** Fishes are an integral component of the estuary food web. In addition, they have a significant societal value for recreation and commercial harvesting.

▸ **Fish-eating birds population dynamics -** Fish eating birds are one of the more visible keystone species in the estuarine ecosystem. Their dependence on fish for food serves as an indicator of the health and status of their prey populations.

D-A.3.6 LINKS FROM STRESSORS TO VALUES

Seven stressors that exert significant impacts on the estuary's ecological and societal attributes were identified for these systems. However, the linkages between ecosystem stressors to the environmental and societal values are complex, and considerable uncertainties remain. As more is learned about how these systems function, these linkages may be changed or new ones included. One aspect of the model is that it is flexible and can be adjusted as new information is available.

▸ ***Altered hydrology*** is one of the predominant stressors on the system. This stress is the result of managing the runoff of the watershed to accommodate agricultural and urban development, along with flood control releases from Lake Okeechobee. Accompanying these hydrologic changes are increased sediment transport, transport of floating freshwater vegetation (Hyacinth and Pistia) into the estuarine portion of the ecosystem, and alterations in water residence time and biological flushing of the estuary. Salinity, a key organizing parameter for the estuary, is directly affected by changes in inflows and tidal exchange. All of these factors combined have been shown to impact indicator species of estuarine health, namely seagrasses and oysters.

▸ ***Physical alterations*** to the ecosystem have also had a significant effect on the presence and abundance of species normally found within these systems. These alterations have occurred through a variety of activities, including shoreline hardening, inlet dredging and stabilization, removal of oyster shell for road bed material, snagging of navigation hazards, decrease in spatial extent of the estuary through construction of barriers [S-79], and the impoundment of salt marshes for mosquito control (on the east coast). Changes in the physical dimensions of the estuaries, most notably in the Caloosahatchee, have significantly reduced the euryhaline portion of the estuary, an important nursery area, feeding area and refugia for juvenile stages of desirable sport and commercial fishes. Construction and operation of the water control structures have interfered with the migration patterns of many estuarine species, and have also resulted in the death of manatees attempting to pass through these structures.

▸ ***Nutrients and dissolved organics*** enter the system as a result of anthropogenic activities in the watershed, primarily agricultural and water management, although urban use of fertilizers is also a contributor. In addition, atmospheric deposition contributes to the nitrogen loading of the system. These constituents interact with alterations in salinities and sediment loading to reduce light penetration which, in turn, leads to declines in seagrasses. The shift in the species composition of benthic invertebrates to more pollution-tolerant organisms is also linked to increases in nutrients.

- ***Toxics***, which include pesticides, fungicides, herbicides, brine from reverse osmosis plants, coliforms from sewage treatment plants (STPs), oils, greases, and mercury are introduced into these systems from urban development, agricultural practices, and boating. Direct toxic effects have been noted on some zooplankton and fish. Indirect effects occur through the process of bioaccumulation or biomagnification through the food web, increasing the toxic load to top predators. The problem of eggshell thinning in pelicans and osprey was the result of bioaccumulation of DDT.

- ***Temperature extremes*** are the result of both rare natural events, such as freezes, and human activities due to discharges from nuclear power plants and STPs. Severe freezes have resulted in the direct decline of mangroves and manatees. In addition, the unnatural congregation of manatees in waters warmed by plant discharges is thought to contribute to the spread of disease and exposure to red tide.

- ***Boating pressure*** is a significant stress to the estuaries through direct impacts such as scouring, wake erosion, and construction of boating channels. In addition, boat collisions are the leading anthropogenic cause of manatee deaths.

- ***Resource harvesting*** of sport and commercial fisheries has impacted the standing stocks of many species where over-fishing has occurred. This in turn impacts those species that depend on fish as their primary food source.

D-A.3.7 SUMMARY

A conceptual model was developed for the St. Lucie and Caloosahatchee Estuaries. The model illustrates major linkages between stressors on the system and ecological and societal values. The purpose of the model is to provide a basis for management decisions on proposed restoration activities and to assist in the development of an integrated ecological monitoring program.

D-A.4 DRAFT BIG CYPRESS REGIONAL ECOSYSTEM CONCEPTUAL MODEL

D-A.4.1 PREPARER

Michael Duever, The Nature Conservancy, Kissimmee, Florida.

D-A.4.2 INTRODUCTION

The Big Cypress region covered by this conceptual model includes the freshwater portions of the area extending from the southern edge of the Caloosahatchee River watershed boundary in Lee, Hendry, and northern Collier Counties, and west of the Everglades, as delimited approximately by L-28 in the north and a diagonal line running from Forty-Mile Bend on Tamiami Trail southwest to the coast. In this region historic water flows were primarily south to the Gulf of Mexico, with minor flows in small creeks that pass through the west coast ridge to the Gulf and somewhat more significant flows east into the Everglades (Klein et al. 1970).

There are three distinct subregions within the Big Cypress Region, based on the kind and degree of development present in each (Lehman 1976). The most pristine area, because the hydrology is largely rainfall-driven, is located within the Big Cypress National Preserve in the southeastern portion of the region (Duever et al. 1986). The Preserve, along with a portion of the adjacent Seminole Indian Reservation to the north, is the Big Cypress subregion that was included in the Restudy Alternatives analyses, although only the eastern portion of this area was affected by components included in the various restoration alternatives. The most developed portion of the area, including both urban and agricultural development, is located on and just east of the coastal ridge from Naples north to Ft. Myers. The rest of the area is a mixture of agricultural lands, suburban and rural communities, and small-to-large natural areas that have been altered to varying degrees by upstream and/or adjacent development. Despite the very different degrees of development in the three subregions, the kinds of stressors and their effects on ecosystem attributes are similar throughout the Big Cypress Region and they differ only in the severity of their impacts.

The Big Cypress region is comparable to the freshwater Everglades in terms of natural community diversity, although the communities tend to form more of a mosaic as opposed to vast expenses of a single community type. The most extensive natural communities in the Big Cypress are distributed throughout the region along very gentle topographic gradients from short-hydroperiod pinelands on the uplands through marshes to long-hydroperiod cypress forests on lower elevations (Craighead 1971, Davis 1943, Duever 1984, Klein et al. 1970). Small open-water ponds are found in scattered deeper depressions, and small islands of hardwood forest occur on elevated sites among or along the edges of deeper herbaceous and forested wetlands. While the Big Cypress is dominated by temperate species, there is a small but unique tropical component that is most prevalent in forested upland and swamp communities (Duever et al. 1986). This component is most abundant and diverse close to the coast, but occurs further inland in association with larger and deeper wetlands, where it is protected from cold winter weather by their canopy and/or the moderating effects of standing water. Under natural conditions, the range of annual fluctuation in water levels above and below ground and the duration of inundation are the primary factors influencing the distribution of these communities, although frequent fires exert a secondary influence by controlling the kinds and structure of their dominant plant species (Craighead 1971, Duever 1984, Harper 1927, Klein et al. 1970). Cypress and marsh communities tend to be more common towards the south as elevations approach sea level, while pinelands are more common in the higher and deeper-sand substrates to the north and on the west coast ridge along the Gulf of Mexico.

D-A.4.3 ECOLOGICAL STRESSORS

The ultimate source of all ecological stressors in the Big Cypress ecosystem is development for agriculture and residential use (refer to figure on page D-A-42). The area's seasonally high water table required the construction of an extensive system of small ditches connected to larger and larger canals to assure that water levels remain below ground throughout the year, in order to make the land suitable for crops and housing (Lehman 1976). The drainage systems produce <u>lowered water tables and shortened hydroperiods</u> for considerable distances in otherwise unaltered lands around and downstream of them (Carter et al. 1973, Klein et al. 1970, Swayze and McPherson 1977). These drier conditions can facilitate upgradient shifts in the characteristics of affected plant communities and an associated increased fire severity (Robertson 1953, Wade et al. 1980). In addition, the water in canals draining these lands normally has a different chemistry than that found in natural Big Cypress waters. This is particularly true in terms of undesirably <u>higher concentrations of nutrients and dissolved minerals</u> (Duever et al. 1986), which can encourage the spread and potential dominance of sites by nuisance native and exotic vegetation. The human response to South Florida's dry season produces an additional hydrologic stress on natural systems in the Big Cypress in terms of <u>lowered water tables and shortened hydroperiods</u>. When weather conditions are dry for extended periods, water use for crops, lawns, etc. goes up substantially, which results in lower than normal water levels in and for considerable distances around the wells that provide this water (Lehman 1976, Rochow 1985). Excessive drawdowns associated with canals and wellfields can produce very significant impacts on native amphibian, fish, and crayfish populations that depend on the presence of at least some inundated wetlands for their survival through the dry season. These drawdowns can also eliminate the standing water that normally protects tropical components from winter freezes (Duever et al. 1978).

Changes in land use associated with agricultural and residential development not only cause habitat loss on the affected lands, but fragmentation of the habitat mosaic. Habitat loss directly impacts the availability of resources required by organisms that utilize these areas. However, the distribution of these habitats across the landscape is even more important because few organisms utilize only one habitat type, particularly in a landscape that can fluctuate seasonally from inundated to completely dry and that may be affected by widespread and sometimes severe fires. Thus, when wetland connections to adjacent uplands are severed, innumerable biologically important flows are interrupted and ecosystem diversity and viability are severely compromised (Forman and Godron 1986, Harris 1984). Fragmentation and habitat loss also affects populations by reducing the spatial extent of their resource base to the point where it is no longer able to support viable populations. Exposure to hazards associated with development also increases dramatically as habitats become smaller and are more and more fragmented.

As development increases in an area, the seasonality and frequency of fire in natural communities becomes increasingly unnatural (Wade et al. 1980). Natural fires were normally most common during the summer wet season as a result of the high frequency of lightning (Duever 1984). However, they were most widespread at the end of the dry season, when the region was at its driest and lightning storms were just beginning to occur. Early in this century, cattlemen greatly increased the frequency of dormant season fires to provide more forage for their cattle during the winter months (Ackerman 1976, Alvarez no date, Kennard 1915). More recently, fire has been suppressed over much of the more developed portions of the area, which has caused unusually severe fires when they finally occur, as they always do eventually (Hofstetter 1984). The lack of fire has allowed succession to proceed in many areas, so that herbaceous communities are being invaded by dense shrub thickets and pine and cypress forests are being invaded by shrubs and hardwoods (Hofstetter 1984).

Exotic plants and animals produce drastic alterations in the composition and structure of natural communities, although many of these changes are poorly documented, such as the impacts resulting from the spread of feral hogs and exotic fish (Crowder 1974, Dineen 1984, Duever et al. 1986, Layne 1984). Some that are well documented include the spread of melaleuca and other exotic plants (Duever et al. 1986, Myers 1975). Some species, such as melaleuca and feral hogs, can readily utilize undisturbed natural communities. However, development has facilitated the invasion of exotics by creating an abundance of disturbed sites that normally would have been recolonized by native species, but these species are now being outcompeted by more rapidly invading exotics (Elton 1958, Odum 1971). In addition, farms and residential areas create new habitats that are more suitable to new species, which then invade adjacent natural areas and impact native populations either directly by predation or indirectly through competition for resources.

Bioaccumulation of mercury and other toxins pose a threat to fauna at all trophic levels in all South Florida ecosystems, including the Big Cypress Region, as discussed under generic issues.

D-A.4.4 ECOLOGICAL ATTRIBUTES / VALUES AND MEASURES

Vegetation community and habitat mosaic. This attribute is affected by all of the stressors except mercury and other toxins, which tend to be more impacting on animal populations than on plant communities. Hydrologic and fire regimes control the character and distribution of the major types of Big Cypress plant communities (Craighead 1971, Davis 1943). The most frequent and widespread hydrologic alterations typically result in reduced depth and duration of inundation, which shifts the affected plant communities upgradient towards shallower wetland types, or with sufficient drainage to upland types (Alexander and Crook 1973, Duever 1984). Fires are more frequent and severe in these drier environments, in some areas resulting in dense stands of fire-tolerant cabbage palms and woody exotics (Gunderson and Loope 1982, Tabb et al. 1976). Drainage can also impact tropical components of the communities by eliminating the moderating effect of standing water on cold winter temperatures (Duever et al. 1978). Less frequent alterations involve increasing depths and/or duration of inundation, which can convert uplands to wetlands and wetlands to aquatic habitats. In some situations, altered hydrology can produce unnatural permanently disturbed habitats that are at times too deeply flooded to support upland vegetation, but for too short a period to produce wetland communities.

Natural communities in South Florida are adapted to surface waters with a chemical composition that contains very low concentrations of dissolved minerals and nutrients. Changes in surface water quality typically involve increased nutrient and mineral concentrations coming from ditch and canal outflows into natural wetlands (Drew and Schomer 1984). These increased concentrations can produce dramatic shifts from diverse herbaceous communities to communities dominated by a few native and exotic nuisance species adapted to high nutrient and dissolved mineral concentrations, such as cattails and primrose willow (Duever pers. comm.).

Dormant season fires and reduced fire frequencies can result in shifts from herbaceous to shrubby communities and from open pinelands and cypress forests to shrub and hardwood dominated forests (Alexander and Crook 1971, Duever 1984). As fuels build up in these sites, the inevitable severe wildfire will eventually occur (Hofstetter 1984), and the sites will most likely be converted to early successional communities dominated by weedy herbaceous, vine and shrub species, a large proportion of which are much less abundant, if even present, in natural communities.

Land use changes reduce the area of affected communities and often eliminate the transitions from one to another, particularly along upland to aquatic hydrologic gradients. Since wetlands have more legal protection and are more difficult to develop than uplands, habitat loss is greatest in historical uplands, although this may not be obvious because new upland habitat is being created by the drainage occurring throughout much of the area. Upland development is also resulting in wetlands becoming more and more isolated from each other as well as from other natural parts of the system, which is in turn affecting their faunal populations and fire regimes.

All of the ecosystem alterations associated with development are facilitating the increasingly rapid spread of nuisance and exotic species throughout the Big Cypress Region landscape (Drew and Schomer 1984, Duever et al. 1986). In many areas, exotic woody vegetation such as melaleuca, Brazilian pepper, or downy rosemyrtle completely dominates what were previously herbaceous communities or open pinelands. Cattails and primrose willow have replaced marsh communities that once supported diverse herbaceous species assemblages. Feral hogs annually "plow" thousands of acres, with unknown impacts on what they are foraging on, but quite visible soil disturbance effects that further exacerbate the spread of exotic plants (Duever et al. 1986, Layne 1984).

Measurements of changes in the vegetation mosaic in terms of <u>community distribution, composition, and acreages</u> would provide a basis for assessing habitat gains and losses in the Big Cypress Region. The above discussion is not meant to be exhaustive, but provides examples of the kinds of changes that would be useful to monitor, particularly in any areas that are established as major restoration sites or are set aside for preservation. Rates of change in these communities in response to increased or decreased levels of stressors will vary from three to twenty or more years depending on community type and the management required to accomplish restoration. Early succession communities tend to respond more rapidly to changes than do later successional communities. Management that directly affects vegetation, such as herbiciding or prescribed fire, will produce more rapid responses than will management actions that indirectly affect it, such as changes in hydrology or a reduction in fire frequency.

Logging of old growth pines, which occurred in the Big Cypress through the 1950s, has removed many of the prime red-cockaded woodpecker nesting trees throughout its range (Ligon 1971, Patterson and Robertson 1981). In addition, conversion to agriculture and housing is eliminating their habitat, and the current altered fire regime is resulting in the invasion of native and exotic woody vegetation into remaining pinelands, which is eliminating the open character of these pinelands that is needed to support this species (Patterson and Robertson 1981, Jackson 1971). <u>Red-cockaded woodpecker nesting and nesting success</u> is recommended as a measure of pineland condition, since this species is dependent upon mature, open pinelands. Suitable habitat should be extensive enough so that it would burn regularly, while having a hydrology that would prevent excessively severe fires. Sites should not support nuisance exotics that would tend to grow up and both eliminate the site's open character and produce fuel loads that would result in excessively severe fires. Response to restoration that increases the suitability of habitat would like be expected within five to ten years, where reestablishing the open character of a pineland is involved, but could be twenty or more years, where young pine stands need to reach large enough sizes to provide suitable nest sites.

Native fish, crayfish, and amphibians. These species are affected primarily by altered hydrology and land use changes, both of which are resulting in habitat loss and fragmentation over large areas of the Big Cypress. Abundance of marsh fishes has been correlated with duration of flooding in the Everglades (Loftus and Eklund 1994), suggesting a decline in fish populations in remaining Big Cypress wetlands where water tables have been lowered and hydroperiods shortened. Habitat fragmentation is particularly damaging to these species, which in more natural settings take advantage of the wet season expansion of surface waters into the surrounding uplands by increasing their numbers and biomass, which then becomes available to wading birds and other predators during the surface water's subsequent retreat during the dry season (Carlson and Duever 1979, Kolopinski and Higer 1969, Kushlan et al. 1975). A poorly known influence on them are exotic fish and amphibian species that have invaded the area, which are both preying on native species and competing with them for resources (Dineen 1984, Duever et al. 1986). Documenting the abundance, distribution, and diversity of these taxa will provide useful measures of how the stressors affecting them are being minimized in protected areas and are being ameliorated in areas being restored. Since these populations show a dramatic annual cycle in their numbers and biomass, responses to increasing or decreasing levels of stressors should be detectable within three to five years.

Wood Stork. The Big Cypress region supported the two largest nesting colonies of wood stork in North America between 1900 and 1965 (Ogden Pers comm.). During that period, 6,000-10,000 pairs nested annually in the Corkscrew colony, the Sadie Cypress colony of Okaloacoochee Slough, and smaller subsidiary colonies. Since 1965, wood stork nesting in Big Cypress has declined and has ranged from less than 500 to 1500 pairs since 1990 (Ogden pers. comm.). The subsidiary colonies have been largely lost. Accompanying the decline in numbers of nesting pairs has been a reduction in nesting success in the remaining colonies. The decline in success is attributed to a change in the timing of the initiation of nesting from November to February (Kushlan et al. 1975, Ogden et al. 1987, Ogden 1994). Delay in nesting until February puts nesting out of sync with seasonal rainfall patterns. With the onset of the wet season, rising water levels decrease food availability before the young storks fledge, causing nestling mortality due to starvation. The reduction in numbers of nesting pairs and nesting success is attributed to the loss of early dry season foraging habitat of the higher elevation wetlands of the Big Cypress region that have been drained and developed. Recovery of fish production in the higher elevation wetlands by raising water tables in preserved areas in the western and northern portions of the Big Cypress basin is expected to halt the decline in wood stork nesting in Big Cypress. A trend of increasing numbers of nesting pairs and nesting success and reestablishment of subsidiary colonies should be evident over a decade time scale after water table recovery.

Florida Panther. The Big Cypress Region supports the only viable population of Florida panthers (Logan 1993). The downward spiral of habitat loss and fragmentation leading to isolation and inbreeding has resulted in a single population struggling to survive in the largest remaining contiguous block of land within its historic range. Seventeen years of monitoring indicate a stable but saturated population in the northern portion of its current range, which encompasses public lands north of I-75 and adjacent private lands (Jansen pers. comm.). Habitat vacancies in southern Big Cypress National Preserve and Everglades National Park have not been filled due to the difficulty of population increase when there are few individuals, at times only a single sex, and infrequent ingress. Panther require dry areas for daytime resting but readily travel through inundated habitats (Jansen 1987). Deer, a preferred prey species, benefit from a hydroperiod that promotes nutritious wetland vegetation (Loveless 1959), and prescribed fire improves the nutritional quality of food used by panther prey species. Stressors for the panther include continued habitat loss, inbreeding, and mercury toxicosis. Whether the panther can survive on only existing public lands is unknown, but further habitat reduction will likely increase its vulnerability to catastrophic events. Efforts to improve genetic diversity have been initiated through the introduction of another cougar subspecies. The sources of methyl mercury, reported as the cause of death of at least one panther and known to compromise normal biological functions, have yet to be confirmed and remedied (Roelke et al. 1991). Habitat protection and restoration of natural hydroperiods with clean water would benefit the panther by providing suitable land for population expansion, as well as an uncontaminated and abundant prey base (Jansen, pers. comm.). Improvements in population size, reproductive success, and mercury body burden would likely take decades to document, given the current small population size, low reproductive rate, and the slow turnover of mercury in the body, although improvements in the prey base could be apparent in less than a decade.

Health of Aquatic Fauna. Potential inputs of mercury and other toxins in agricultural and urban runoff water, which may be needed for hydropattern restoration in the Big Cypress, could result in reduced health, behavioral and physical abnormalities, and loss of reproductive vigor unless measures are taken to restrict loads of these toxins in waters flowing into natural areas. Measures of aquatic faunal health that reflect responses to the mercury and pesticide inputs include body burdens of mercury and other toxins in representative species.

D-A.4.5 HYDROLOGIC PERFORMANCE CRITERIA FOR RESTORATION

Successful protection of undisturbed areas and restoration of disturbed areas require the establishment of hydrologic targets that define the desired characteristics of a site's hydrologic regime, and hydrologic measures that evaluate the current status of the site relative to the target. In the portions of the Big Cypress that are included in both the Natural System Model (version NSM4.5F) and the South Florida Water Management Model (SFWMM), NSM conditions were defined as the hydrologic target. The following performance measures were used to evaluate the hydrologic condition of various distinct portions of the area as they were shown to be affected by proposed restoration Alternatives included in a modified version of the SFWMM. Plans are underway to create an expanded version of the SFWMM that will include all of the Big Cypress Region. At the moment there are no plans to create a NSM for the area, although this would be more feasible after the SFWMM is available, since the original NSM was created by modifying the existing SFWMM. Until this model is available, it will be difficult to accurately utilize the following performance measures for the remaining portion of the Big Cypress. Information on the hydrologic regimes of the major Big Cypress freshwater plant community types are described in Duever (1984), and these could be used as interim hydrologic targets for particular communities.

All aspects of a plant community's hydrologic regime are significant in determining its taxonomic and structural characteristics, as well as its distribution across the Big Cypress landscape. The annual duration of inundation, or hydroperiod, is the most important aspect of the hydrologic regime (Duever 1984), largely because of South Florida's minimal topographic relief and its distinct wet and dry seasons. Short hydroperiods eliminate wetland species that are intolerant of the more frequent and severe fires on sites that are dry most of the year, while long hydroperiods eliminate upland species intolerant of extended inundation in low areas (Duever et al. 1978). Maximum and minimum water levels are also important. Wet season water depths can eliminate emergent species that cannot tolerate extended periods of being submerged. The extent of dry season water level declines can influence the frequency and severity of fires entering wetlands, particularly those with organic soils, which maintain a relatively moist substrate and microclimate as long as they are in contact with the water table (Coultas and Duever 1984). During the wet season, water naturally moved as sheet flow across the Big Cypress (Klein et al. 1970). The fact that the water is moving is important, particularly in terms of the resulting water column mixing, which produces a very different water quality than is found in ponded water.

Duration of inundation was evaluated using a number of performance measures. One that provided a spatial perspective of hydroperiod was the percentage of acres within a defined area with a mean hydroperiod for the 31 year simulation that was within 30 days (longer or shorter) of NSM conditions. Another compared average hydroperiod for the 31 year simulation in a specified area in terms of the absolute difference between NSM and current or proposed conditions, which is divided by 100 and then subtracted from 1. This deviation was almost always a reduction in hydroperiod, but any deviation is documented by using the absolute value for the deviation. Another perspective is provided by determining the absolute difference in the average duration of individual flooding events for NSM compared to current or proposed conditions in a defined area, dividing this difference by the NSM duration, and subtracting this value from 1.

Deviations from NSM water levels above and below ground were evaluated by examining the normalized weekly stage-duration curve from a 31 year simulation for a defined area. The performance measure involved examining the current or proposed condition stage-duration curve and determining its maximum vertical deviation from the NSM curve, and dividing this value by the maximum vertical range of NSM water level fluctuation at the site. The reason for dividing the absolute deviation by the maximum NSM water level fluctuation is that a certain degree of deviation in an area with a large natural fluctuation would be less significant than the same degree of deviation in an area with a small natural fluctuation. Typically, the greatest deviation occurred when the water table was declining through the first foot or two below the ground surface, it was smallest at its lowest point on the hydrograph, and it was relatively small when the water table was above ground.

Documenting total flows during the wet and dry season provides a measure of water movement across a defined boundary and how it changes in response to proposed hydrologic alterations in a particular portion of the Big Cypress. The absolute deviation between NSM and current or proposed condition flows was determined first, this value was divided by NSM flows, and the resulting value subtracted from 1. Initially flows were evaluated separately for the wet and dry season, so that the greater volumes of water moving during the wet season wouldn't overshadow the smaller dry season flow volumes. Simple additive equations were then developed for a flow cross-section to combine the wet and dry season information.

In the final analyses, all of the performance measures for a defined area were combined in a simple additive equation. Since there could be three measures for flooding duration and only one each for water level and flows, this automatically weighted flood duration more strongly than either of the other two components of the hydrologic regime.

It is important to be aware that the above performance measures are based on long-term averages, and there is a great deal of natural year-to-year variability in these values. In addition, the same types of communities vary substantially from one place to another, because of differences in their setting and site history. Even though extreme environmental events can have major affects in shaping natural communities, they don't normally produce shifts from one community type to another because the overall ecosystem has evolved in the context of these events.

D-A.5 DRAFT EVERGLADES RIDGE AND SLOUGH CONCEPTUAL MODEL

D-A.5.1 PREPARER

John C. Ogden, South Florida Water Management District, West Palm Beach, Florida.

D-A.5.2 INTRODUCTION

As natural systems, the Ridge and Slough landscape features of the Everglades were extensive, long-hydroperiod, freshwater marshes, characterized by low-velocity "sheet flow", moderate to deep organic soils and sawgrass "ridges (Davis et al. 1994, Gunderson 1994, Gunderson and Loftus 1993, McVoy, Park & Obeysekera in prep.)". The ridge and slough systems were dominated by sawgrass strand (Cladium), water lily, and wet prairie (Eleocharis) communities. A spatially variable mosaic of discreet tree islands occurred throughout, ranging from widely spaced in the central Everglades to more densely distributed in the Loxahatchee basin and Shark Slough. The Ridge and Slough systems modeled here are defined by the portion of the Everglades basin where there were Loxahatchee Peat soils (McVoy, Park and Obeysekera, in prep.; the combined "wet prairie/slough, tree island, sawgrass mosaic" and "sawgrass dominated mosaic" in Davis et al. 1994). These sloughs made up the deeper central portions of the total Everglades basin, and occurred to a more limited extent in a series of much smaller scale flow systems located on both the eastern and western flanks of the Shark Slough in the southern Everglades (Taylor, East, Middle, Lostman's sloughs). The ridge and sloughs were principal centers for primary and secondary production and inter-annual survival of aquatic organisms in the freshwater wetlands of southern Florida.

The major, known alterations in the ridge and slough systems have been caused by changes in land use, drainage and water management practices in south Florida (Davis and Ogden 1994, Science Subgroup 1993). The effects from these regional "drivers" include compartmentalization and reduced spatial extent of the natural system, loss of organic soils, altered water depth, distribution and flow patterns, altered water chemistry, and the introduction of exotic species. It is the effects from these "stressors" which are modeled in the conceptual ecological model for the ridge and slough systems, which is presented here.

D-A.5.3 THE SOCIETAL DRIVERS, ECOLOGICAL STRESSORS, AND ECOLOGICAL EFFECTS.

The workshops of the SERA Natural Systems Team and the C&SF Restudy Alternative Evaluation Team have identified four major categories of societal influence (drivers) on the Everglades Ridge and Slough systems, leading to five major ecological stressors. The combined effects from these stressors explain much of the ecological changes which have occurred in the ridge and slough systems (refer to figure on page D-A-56). The four societal drivers and their respective stressors, and the ecological effects resulting from the stressors, are as follows.

Urban and Agricultural Expansion. Drainage of wetlands, and the subsequent conversion of slough habitat into agricultural and urban uses has **reduced** the total **spatial extent** of the ridge and slough system in the main Everglades from 490,000 ha in the pre-drainage system to 365,000 ha in the current system (Davis et al. 1994). The biological and physical effects from this 26% loss in spatial extent include, (a) a substantial reduction in habitat options for wildlife, and (b) a reduction in the system-wide levels of primary and secondary production.

Space was the one physical characteristic of the south Florida wetlands that was necessary for all other physical and ecological components of these systems to be in place. The broad spatial extent of the pre-drainage sloughs was essential for collecting and storing the amount of regional rainfall that was required to maintain the ecological vigor of these systems. Large spatial scale provided the foundation for the processes that created and maintained a mosaic of habitats in a low profile terrain (Craighead 1971, DeAngelis & White 1994). Disturbances, such as fire, freezes, tropical storms, and animal related impacts (e.g., an abundance of alligator-created ponds and trails) served to increase the complexity of habitats, as well as the range of habitat choices for species of wildlife with both small and large home ranges (Craighead 1968, DeAngelis 1994, Duever et al. 1994, Gunderson & Snyder 1994, Davis & Ogden 1994). Extensive space was necessary for supporting robust numbers of animals requiring extensive feeding or hunting ranges throughout different seasons and a range of hydrological conditions For example, the location of feeding and nesting sites for white ibis and other wading birds, snail kites, and other common aquatic birds shifted across large spatial scales and across seasons and years, in response to variability in hydrological patterns (Kushlan 1979, Bennetts et al. 1994, Hoffman et al. 1994, Ogden 1994). The large number of ponds and depressions occurring over an extensive region allowed for comparatively sedentary species such as the alligator to maintain very large, regional numbers (Craighead 1968). Greater space enabled the system-wide aquatic production in a nutrient-poor ecosystem necessary to support large numbers of wading birds and alligators (Browder 1976, Mazzotti and Brandt 1994).

(2.) **Influences from Industrial and Agricultural Practices**. Increased loads of Phosphorus (P) and Mercury (Hg), originating as bi-products from an array of agricultural and urban industrial practices, were identified as the two alterations in **water quality** which have been demonstrated or hypothesized, respectively, to have had the greatest ecological significance in the slough systems (Roelke et al. 1991, Spalding & Forrester 1991, Lange et al. 1994, Browder et al. 1994, Davis 1994, Frederick et al. 1997). Increased phosphorus loading in a low-nutrient system has, (a) caused a substantial expansion of "nutrient-loving" plants (monocultures of cattail) into other communities, (b) contributed to shifts in the species composition in periphyton mats, from communities dominated by green algae/diatoms to communities dominated by blue-green algae, and (c) contributed to reductions or alterations in primary and secondary production patterns. Increased levels of environmental mercury, and the conversion to the toxic methyl mercury form, has considerable potential to substantially reduce survival rates, and alter behavior patterns, for omnivorous and carnivorous animals dependent on wetland food chains.

(3.) **Water Management Practices**. All five of the major ecological stressors acting on the slough systems (reduced spatial extent, the introduction and spread of degraded water, **reduced water storage capacity, compartmentalization**, and the introduction and spread of exotic species) have had part or all of their origins in water management practices. Major objectives of water management have included water supply and flood control, which have been achieved by means of a complex system of structural and operational modifications to the natural system. These modifications have, (a) contributed to the substantial reduction in spatial extent, (b) provided a network of canals and levees which have accelerated the spread of degraded water and exotic species, (c) greatly reduced the water storage capacity within the remaining natural system, (d) altered sheet flow velocities and directions, and (e) created an unnatural mosaic of impounded and over-drained marshes in the Water Conservation Areas (Science subgroup 1993, Davis and Ogden 1994, Light and Dineen 1994, Fennema et al. 1994).

Ecological effects from (a) and (b) are summarized in (1) and (2) above. The combined effects from reduced water storage capacity, altered sheet flow patterns and compartmentalization have, paradoxically, included both a reduction in the duration of annual and multi-year hydroperiods and an increase in the frequency of unnatural high water events.

Shortened hydroperiods (i.e., an increase in the frequency and duration of surface water dryouts) have resulted in a substantial increase in the frequency and extent of over-drained marshes, primarily during dry season months. Over-drained marshes have contributed to a broad array of adverse ecological impacts, including the spread of woody species of plants into marshes, reduced alligator nesting effort, reduced levels of aquatic production, reduced survival by aquatic organisms over multi-year periods, and considerable loss of peat soils due to increased frequencies and intensities of fire and increased levels of soil oxidation (e.g., Craighead 1971, Davis and Ogden 1994, Fleming 1991, Gunderson and Loftus 1993, Loftus et al. 1990, Loftus et al. 1992, Loftus and Eklund 1994, Mazzotti and Brandt 1994, Myers 1983, Stober et al. 1996).

The unnaturally distributed mosaics of impounded water in the southern portions of the WCAs, caused by compartmentalization, have contributed to the flooding of tree islands, have altered marsh community structure, and have caused an artificial re-distribution of the centers of aquatic production and animal survival throughout the WCA portion of the ridge and slough system (Armentano 1996, Bancroft et al. 1994, Davis et al. 1994, Fennema et al. 1994, Frederick and Spalding 1994). The break-up of the large, traditional wading bird nesting colonies and relocation of smaller, less successful colonies to the WCAs, are hypothesized to be responses by wading birds to the combined affects of marsh drainage and the relocation and fragmentation of the region's aquatic production and survival centers (Ogden 1994).

Societal influences on the species composition of regional floras/faunas. The introduction, both intended and unintended, of large numbers of **non-native species** of plants and animals that have been brought into south Florida because they have been considered to be desirable additions to the region, from the perspective of a wide range of human values, has resulted in substantial alterations to the Everglades sloughs. The most blatant examples affecting the sloughs have been, (a) the invasions by Melaleuca, and the conversion of extensive marshes into woody swamps (Bodle et al. 1994, Laroche and Ferriter 1992), and (b) the spread by 15-20 species of introduced fishes throughout much of the region of the ridge and slough systems (Courtenay 1994, Robertson and Frederick 1994). Although the ecological consequences of these fishes has been largely unmeasured, it must be assumed that their presence has substantially altered the characteristics of marsh fish communities.

D-A.5.4 CRITICAL ECOLOGICAL PATHWAYS

The principal, broad-scale ecological responses from the combined affects of the five major ecological stressors acting on the ridge and slough systems have been, (a) a substantial alteration and degradation in the natural patterns of plant community composition and structure, and (b) substantial changes in the distribution, and reductions in abundance, among many of the native animals that are dependant on aquatic habitats and food chains. The relative contribution made by each of the stressors, along the different pathways shown in the model, to these two primary responses is not well known. For example, the presence of physical and biological thresholds, some of which may have been crossed as a result of the affects of the stressors, have yet to be demonstrated for most functions and relationships in the sloughs (an exception might be the 10 ppb value for Ph). Never-the-less, current understandings of the ridge and slough systems, as expressed by the NST and AET workshop participants, suggest that four ecological pathways have been most important for explaining how these two principle, broad-scale, ecological responses have been linked to the stressors. These four pathways are:

(1.) The pathway that links the reduction in water storage capacity and the substantial increase in the extent and frequency of over-drained marshes (shortened hydroperiods), with an array of ecological effects characterized by a spread in woody vegetation, reduced numbers of nesting alligators, reduced marsh production, reduced dry season survival by aquatic organisms, and the loss of peat soils.

(2.) The pathway that links compartmentalization, and the adverse affects that levees have on water depth/distribution patterns and sheet flow, with altered patterns of nutrient cycling and reduced marsh production, and relocated animal distribution, production and survival centers.

(3.) The pathway that links the reduction in water storage capacity, compartmentalization and the adverse affects of regulatory releases, with flooded tree islands and flooded alligator nests.

(4.) The duel pathways that link degraded water quality and the affects of canals with increased phosphorus loading, resulting in the spread of cattail monocultures, degraded periphyton communities, and reduced marsh production.

D-A.5.5 ECOLOGICAL ATTRIBUTES AND MEASURES.

The NST and AET workshops recommended seven ecological attributes of the Everglades ridge and slough systems, which, collectively, will provide the best measure of system responses to restoration projects (Fig. X). The model shows how each attribute is linked to one or more stressor. The recommended measures for each attribute should be treated as priority components for a comprehensive ecological monitoring program.

(1.) Peat Soils. A recovery of more natural patterns in the duration of uninterrupted surface flooding, and in water depths, should result in the return of pre-drainage rates of accretion for peat soils. Conversely, unnatural rates of loss of organic soil due to oxidation and excessive fires should be curtailed.

(2.) Community of Marsh Fishes, Invertebrates & Herps. Improved water quality, longer hydroperiods, improved patterns of nutrient cycling and primary production, and reductions in the influences of exotic fishes, should be reflected by measures of the composition, size structure and abundance of these animals.

(3.) Tree Islands. Reductions in the adverse affects of flooding, fire, and exotic plants should be reflected by measures of tree island distribution, and by the species composition and structure of woody plants on the islands.

(4.) Marsh Plant Communities. Elimination of the adverse impacts due to excessive fire, soil oxidation, shortened hydroperiods, unnaturally deep impoundments, overdrained marshes, the spread of exotic plants, and degraded water quality should be reflected by measures of the distribution, composition and structure of the dominant marsh communities in the sloughs.

(5.) Alligators. An increase in the abundance and density of alligator nests and active alligator ponds is an expected response from lengthened hydroperiods, increased marsh production rates, and reductions in wet season regulatory releases and the unnatural affects of impoundments.

(6.) Periphyton. Improvements in water quality and in the depth and duration of flooding should be reflected by shifts in species composition and production rates in the periphyton communities.

(7.) Wading Birds. The size, timing and location of wading bird nesting colonies, as well as the occurrence and frequency of "super colonies", should reflect improvements in foraging habitat options under a range of climatological conditions, in marsh production rates, survival rates of marsh organisms during dry periods, and in the location of the major production and survival centers in the slough systems.

D-A.5.6 HYDROLOGICAL PERFORMANCE MEASURES.

The four critical pathways (above) suggested by the Everglades ridge and slough model are driven by hydrological stressors (over-drained marshes due to reduced storage capacity; unnatural depth-distribution patterns due to levees; wet season flooding due to regulatory releases and the affects of canals and levees; increased phosphorus levels due to agricultural practices and canals). These pathways suggest that the most important hydrological targets for meeting the ecological objectives of the SERA and Restudy projects are, (a) reduction in the frequency, duration, extent and magnitude of marsh dryouts during dry seasons, (b) reduction in the unnatural spatial mosaics of deep impoundments and over-drained marshes, reductions in the duration and unseasonable timing of unnatural high water events during wet seasons, and (d) reductions in the input and rapid distribution of phosphorus. The shortened dry-season hydroperiods characteristic of the managed system are a response to substantially reduced water storage capacity in the system, coupled with the affects of compartmentalization. The unnatural mosaics of deep and shallow water are caused by compartmentalization; more specifically, by the network of levees and the operational schedules associated with the WCAs. The unnatural wet season depth patterns have been due to the combined affects of water storage in WCA-3A, and regulatory releases through the S-12s. These three stressors working in concert have caused a loss of natural patterns of inter-seasonal and inter-annual water depth distribution and depth, which is thought to have substantially disrupted the pulses in marsh production that once characterized the natural system. The increased phosphorus loading has been due to the rapid transport of water with elevated phosphorus levels into much of the Everglades ridge and slough system.

Of these four priority hydrological targets, three are characterized by measures of water depth, and the duration and timing of surface and ground water flooding. For these three, hydrological performance measure targets can be established, based on regional hydrological patterns predicted by the Natural Systems Model. These performance targets, and a suggested order of priority relative to the magnitude of the ecological issues associated with each, are as follows.

Priority 1. The highest priority for ecological restoration of the Everglades ridge and slough systems is the establishment of annual and interannual patterns in the duration of uninterrupted surface flooding, which are generally consistent with predictions of the NSM, in Everglades National Park and the WCAs. Included in this priority is the increase in duration of flooding in the overdrained, northern ends of the WCAs without an increase in flooding in the southern WCAs, and a recovery of the pre-drainage patterns of multi-year hydroperiods in Shark Slough.

Priority 1 Measure. For the 30 year period of record, compare patterns of uninterrupted surface water flooding for cells at key indicator regions. The performance criterion is the difference between the duration patterns shown by the NSM and the 2X2 simulations for each plan alternative. The target is a mean difference of zero. Examine annual hydrographs to insure trends are correct and that the annual drydown in any given year does not occur before the time indicated by the NSM.

Priority 2. Elimination of compartmentalization effects, characterized by unnatural mosaics of deep and shallow water across levee alignments, and by loss of sheet flow.

Priority 2 Measure. Compare monthly surface and ground water depth patterns for selected sets of cells representing opposite sides of levees, for all major structural divides within the WCAs, and between WCA 3 and Everglades National Park. The performance criterion is for water depths between paired sets of cells to not differ more than 0.2 foot during any given month, and for these depth patterns to be consistent with NSM predictions. For sheet flow, compare numbers of miles of levees and canals internal to the ridge and slough systems, and separating the ridge and sloughs from adjacent wetlands (i.e., sawgrass plain; Big Cypress).

Priority 3. A third priority in the ecological restoration of the Everglades sloughs is the elimination of regulatory schedules and other operational practices, and internal levees, which cause unnaturally deep water patterns, primarily during wet seasons.

Priority 3 Measure. For the 30 year period of record, compare monthly patterns of surface water depth for cells at key indicator regions. The performance criterion is the difference between the depth patterns shown by the NSM and the 2X2 simulations for each plan alternative. The target is a mean difference of zero.

Examine monthly depth pattern graphs to insure trends are correct for timing and location, relative to NSM patterns.

D-A.6 DRAFT MARL PRAIRIE/ROCKY GLADES CONCEPTUAL MODEL

D-A.6.1 PREPARER

Steven M. Davis, South Florida Water Management District, West Palm Beach, Florida.

D-A.6.2 INTRODUCTION

In 190,000 ha of higher-elevation, freshwater marshes on either side of Shark River Slough, water levels typically drop below the ground surface each year (Davis et al., 1994). Consequently peat accretion is inhibited, and substrates consist either of marl produced by periphyton mats, or exposed limestone bedrock with solution holes (Gleason, 1972). The landscape consists of a mosaic of wet prairie, sawgrass, tree island, and tropical hammock communities that support a high diversity of plant species (Olmstead and Loope, 1984). The ephemeral characteristics of the hydrology of marl prairies and rocky glades pose stresses to the wetland animal communities regarding survival through the dry season when standing water is usually absent (Loftus and Eklund, 1994; Loftus et al., 1990). In that respect, the American alligator represents a keystone species in the marl prairie/rocky glades because alligator holes provide important refugia for aquatic fauna during dry periods (Craighead, 1968).

D-A.6.3 ECOLOGICAL STRESSORS

The dominant sources of stressors on the marl prairie/rocky glades ecosystem are water management practices and agricultural and urban development (refer to the figures on pages D-A-72 &73). The water management system has altered hydropatterns of remaining wetlands primarily through the lowering of water tables and through the unseasonable regulatory release of water from upstream (Van Lent et al., 1993). A network of canals and levees, particularly the C-111 system, has resulted in the compartmentalization of the remaining marl prairie/rocky glades wetland system. The canals and pump stations are conduits for inputs of nutrients, mercury, other toxins, and exotic fishes into the remaining wetland system

Agricultural and urban development represents a direct loss of spatial extent of the marl prairie/rocky glades wetland system through conversion of marshes to farmland and housing (Davis et al., 1994). Development provides potential sources of nutrients, mercury and other toxins to the natural system via runoff water that may need to be captured and stored for hydropattern restoration.

<u>Shortened hydroperiod (duration of uninterrupted flooding)</u>. Much of the marl prairie/rocky glades remains dry most of an average year under present conditions,

compared to a duration of uninterrupted flooding averaging nine months pre-drainage as indicated by the Natural System Model (Van Lent et al., 1993; Fennema et al., 1994; VanZee, in preparation). Shortened hydroperiod directly affects ecosystem food webs through the 1) decrease in diatoms, desmids, and other green algae associated with the periphyton mat and the related reduction of the primary production food base (Browder et al., 1994), 2) reduced secondary production and altered species composition of fish based on comparisons of long and short hydroperiod sites in Shark River Slough (Loftus and Eklund, 1994; Loftus et al., 1990; Turner et al., 1999 in press) and possibly crayfish, 3) reduced pupolation density and altered species composition of small herpetofauna, based on abundance in short-hydroperiod habitats in relation to rainfall and water levels on Big Pine Key (Diffendorfer et al., in preparation; Dalrymple, 1987; Dalrymple, personal communication), 4) loss of the potential for hypothetical wading bird and wood stork foraging during the early dry season (Fleming, personal communication in Ogden, 1994), and 5) decline in the American alligator population in the landscape where it was once abundant (Craighead, 1968; Mazzotti and Brandt, 1994). Shortened hydroperiod directly affects plant community and habitat structure, in addition to the already noted alteration of the periphyton mat and filling in of alligator holes, by enabling the invasion of woody plants such as willow and exotics such as Brazilian pepper and melaleuca in a naturally herbaceous landscape (Armentano et al., 1995; Jones and Doren, 1997), and by altering the plant species composition of macrophyte vegetation toward more terrestrial plant species (Hofstetter and Hilsenbeck, 1980; Hilsenbeck et al., 1979). Shortened hydroperiod indirectly affects plant community and habitat structure through altered fire regime: hotter and more severe fires due to the prolonged dry season (Gunderson and Snyder, 1994) further alter herbaceous plant species composition and reduce plant community heterogeneity by burning out hardwood hammock tree islands (Loope and Urban, 1980). Shortened hydroperiod, in combination with increased drought severity, threatens Cape Sable sparrow reproductive success and survival in the marl prairies to the east of Shark River Slough by increasing the frequency and severity of nest-destroying fires, or by enabling the invasion of woody plants in the absence of fire (Pimm, 1995)

<u>Increase in drought severity</u>. In a system where water levels typically fall below the ground surface each year, remnant pools of standing water in solution holes and alligator holes during the dry season are critical to the survival of aquatic and amphibious fauna such as fish, crayfish, herpetofauna, and alligators (Loftus et al., 1992; Mazzotti and Brandt, 1994; Diffendorfer et al., in prep.; Dalrymple, 1987; Dalrymple, personal communication). When dry conditions are prolonged, and minimum water levels during a dry season fall below the bottoms of the solution holes and alligator holes, the function of these dry season refugia is diminished or eliminated.

Wet season water level reversals. Field observations indicate that when water depth drops to less than 0.2 feet during a period of flooding, aquatic fauna population densities decline, survivors retreat to refugia in solution holes or alligator holes, and population recovery is slowed (Loftus and Eklund, 1994; Loftus, personal communication).

Drying pattern reversals due to upstream regulatory releases. Reversals in the seasonal timing of water level recessions due to regulatory releases from WCA3A detrimentally affect nesting density and success of the endangered Cape Sable sparrow (Pimm, 1995). Drying pattern reversals have been particularly detrimental to sparrow nesting in the marl prairies to the west of Shark River Slough, in an area that is affected by water releases from the S-10 A and B outflow gates from Water conservation Area 3A. Unnaturally high flow volumes to the west of Shark River Slough, rather than via Northeast Shark River Slough under NSM conditions, exacerbates the problem of the sparrow. The Cape Sable sparrow depends on predictably dry conditions during its spring nesting period which corresponds to the late dry season (Pimm, 1995). Drying pattern reversals and their effects on the sparrow are analyzed as an endangered species issue.

Increased nutrient inputs. Agricultural and urban runoff water from the lower east coast that may be needed for hydropattern restoration is anticipated to bring with it increased inputs of phosphorus, nitrogen and other nutrients. Cattail has already dominated portions of Taylor Slough downstream of the Park road since pump station S332 commenced to deliver canal water to Taylor Slough (Davis, personal observation). A probable effect of nutrient additions to the marl prairie/rocky glades would be the loss in the periphyton mat and the dominance of blue-green algae, with resulting reductions in the primary production food base and reductions in marl substrate accretion (Browder, 1994).

Compartmentalization. The levees that bound and dissect the marl prairie/rocky glades on the east side of the Everglades, and the C-111 system in particular, may create barriers that genetically isolate populations of aquatic fauna, as demonstrated by the genetic structure of mosquitofish and grass shrimp in the Water Conservation Areas compared to Everglades National Park (Trexler et al., in review). Canals adjacent to the levees provide corridors of permanently flooded, deep-water habitat that would not otherwise occur in the marl prairie/rocky glades. These corridors allow the expansion of exotic and higher trophic level fishes into areas where they could not survive naturally (Howard et al., 1995). The prevalence of higher trophic fishes in the canals diminishes the value that this habitat might otherwise serve as a dry season refugium for aquatic and amphibious fauna.

Loss of spatial extent. The conversion of eastern portions of the marl prairie/rocky glades to agriculture and housing has reduced the spatial extent of primary production that provides the base of the food webs of fish, crayfish, herpetofauna, alligators, and wood storks and wading birds. The spatial loss of the aquatic habitat has also directly reduced populations of these organisms. The extent of loss in production and aquatic habitat is directly proportional to the spatial extent of the area that has literally been taken out of production as wetland (Davis et al., 1994). Loss of spatial extent may have reduced the range of habitat options that are available at any given time for faunal populations (DeAngelis and White, 1994), including nesting by the Cape Sable sparrow nesting (Pimm, 1995) and potential foraging by wood storks and wading birds (Fleming, personal communication in Ogden, 1994).

Introduction of exotic plants. Melaleuca, Brazilian pepper and Australian pine are the three most widespread exotic plant species that have spread into native plant communities of the marl prairie/rocky glades, due to their introduction combined with shortened hydroperiod which allows their expansion (Olmstead and Loope, 1984; Armentano et al., 1995; Jones and Doren, 1997).

Burning practices. Burning practices, particularly from illegally set fires, have shifted the seasonal timing of fires from the May-June early wet season, due to lightning strikes, to the winter-spring dry (Gunderson and Snyder, 1994). Fire severity has been exacerbated by shortened hydroperiod and increased drought severity. The road access provided by levees contributes to fire ignition by humans by allowing arsonists access to the marshes and by creating a source of ignition from vehicle sparks (Burzycki, personal communication). Intense, dry season fires have burned out hardwood hammock tree islands in the marl prairies and rocky glades to the east of Shark River Slough. Fire hazard due to over-drainage also poses a threat to Cape Sable sparrow nesting success and survival in the marl prairies to the east of Shark River Slough.

D-A.6.4 ECOLOGICAL EFFECTS OF WATER MANAGEMENT: CRITICAL LINKAGES BETWEEN STRESSORS AND ATTRIBUTES

Four major causal pathways appear to account for the decline in the ecological values of the marl prairies and rocky glades as a result of water management-induced stressors. Each pathway, other than that of the Cape Sable sparrow, has been most severely impacted in the marl prairies and rocky glades to the east of Shark River Slough.

1) The periphyton mat has been altered in ways that reduce its contribution to aquatic food chains and marl formation. Diatom, desmid and other green algal components of the periphyton mat have decreased as a result of severely shortened hydroperiod. The mat is lost entirely and replaced by non-mat-forming bluegreen algae as a result of nutrient additions in pumped inflow water.

2) The American alligator has been mostly eliminated, due to severely shortened hydroperiod and lowered water table, from the landscape where it was once most abundant. Alligator holes in depressions in the limestone bedrock have silted in with organic debris and no longer function as dry season refugia for aquatic fauna. Their loss has decreased the heterogeneity of vegetation habitat and micro-topography.

3) The marsh fishes, herpetofauna and probably other aquatic fauna of the marl prairies and rocky glades can maintain only diminished population density and secondary production given the shortened hydroperiod and lowered water table, the altered periphyton mat, the loss of dry season refugia in alligator and solution holes, and the physiological stress due to wet season water level reversals.

4) The vegetation community mosaic has lost heterogeneity and changed in species composition due to community shift due to shortened hydroperiod and lowered water table, the loss of alligator holes, tropical hammock tree island burn-out due to altered fire regime, woody plant invasion, and the spread of exotic plants.

5) The Cape Sable sparrow is limited in reproductive success and population size by drying pattern reversals from upstream water releases to the west of Shark River Slough. To the east of the Slough, the sparrow is threatened by shortened hydroperiod and lowered water table, which result either in increased fire frequency and severity, or in woody plant invasion in the absence of fire.

D-A.6.5 ECOLOGICAL VALUES / ATTRIBUTES AND MEASURES

Periphyton mat. The periphyton mat of attached algae plays a key role as a food chain base (Browder et al., 1994), as habitat structure (Loftus, personal communication), and as the source of marl sediments (Gleason, 1972) in the marl prairies and rocky glades. Species composition of the periphyton is a sensitive indicator of both hydrologic conditions and water quality (Browder et al., 1994). Severely reduced hydroperiod in the marl prairies and rocky glades results in a decrease in the diatom, desmid and other green algal species in the periphyton mat, leaving mostly mat-forming blue-green algae that are less valuable as food sources for consumers (Browder et al., 1994). Nutrient enrichment, that may accompany the inflow of canal water, results in the loss of mat-forming species altogether and replacement by non-mat-forming blue-green algae (Browder et al., 1994). Measures of periphyton communities that indicate recovery due to lengthened hydroperiod and potential impacts of nutrient enrichment include aerial coverage, species composition, biomass, and primary productivity rates of periphyton mats of the marl prairies and rocky glades.

Marl substrate. Mat-forming calcitic algae deposit the marl substrate that is characteristic of the marl prairies (Gleason, 1972; Browder et al., 1994), where hydroperiod is too short for the accretion of peat soils. Most of the plant communities described by Olmstead and Loope (1984) and Gunderson (1994) for this region are supported by the marl soils. The dependence of marl deposition on the productivity of the calcitic periphyton mat indicates that the negative impacts of shortened hydroperiod and nutrient enrichment that are noted above for the periphyton mat would also adversely affect the rate of marl accretion. Measures of the marl substrate that should reflect responses to hydroperiod, and nutrients and restoration efforts include marl distribution and depth and marl accretion rate.

Vegetation mosaic and diversity. A unique feature of the marl prairies and rocky glades is the extremely high species richness of their flora. Within the mosaic of low-stature graminoid communities, sawgrass and muhly grass dominate, although more than 100 species of mostly herbaceous plants have been reported (Olmstead and Loope, 1984). The higher-elevation tropical hammock and pine forests that occur as islands within the prairie landscape support flora of West Indian origin that are unique to south Florida, other than the Keys, and that contain the highest number of rare and threatened plant species in south Florida (Gunderson, 1994). The plant communities of the marl prairies and rocky glades have been impacted by man through drainage, exotic invasion and burning practices. Tree island burn-out (Loope and Urban, 1980), shifts to more terrestrial plant associations in the graminoid communities (Hofstetter and Hilsenbeck, 1980; Hilsenbeck et al., 1979), loss of the vegetation heterogeneity associated with the micro-topography of alligator holes (Craighead, 1968), and woody plant invasion of the graminoid communities (Armentano, et al., 1995) have accompanied shortened hydroperiods and lowered water tables. These effects are exacerbated by the spread of exotic trees (Olmstead and Loope, 1984; Armentano et al., 1995; Jones and Doren, 1997) and by dry season burning practices (Gunderson and Snyder, 1994), particularly from illegally-set fires. Measures of vegetation responses to stressors and restoration efforts in the marl prairies and rocky glades include the spatial cover and species composition of graminoid and tree island communities .

Cape Sable sparrow. The Cape Sable seaside sparrow is endemic to the marl marshes of the southern Everglades, where it is listed as an endangered species. The three major breeding colonies of the sparrow include the western sub-population in marl marshes to the west of Shark River Slough, the eastern sub-population to the east of mid Shark River Slough, and the central sub-population to the east of the southwest Slough (Pimm, 1995). The sparrow nests during the dry season months, mostly during April–June, in sites free of standing shrubs or trees. The construction of nests approximately 10 cm above the ground at the bases of tussocks of muhly grass and other marsh graminoids makes the sparrow vulnerable both to spring wildfires and unseasonable water depth increases (dry season water level reversals). Successful nesting requires approximately 45 days of nearly dry conditions without fire. Dry season water level reversals have been a particular problem to the nesting success of the western sub-population, where regulatory water releases through the S-12 A and B outflow gates of Water Conservation Area 3A contribute to the reversals and subsequent nest drowning (Pimm, 1995). The eastern sub-population occupies an over-drained region of marl prairie subject to spring wildfires or to invasion of woody vegetation. The central population is the most stable because of its remote location, although it is vulnerable to infrequent, naturally-occurring dry season fires. Measures of sparrow populations that reflect responses to stressors and restoration measures include nesting distribution, density and success.

Aquatic fauna. The aquatic fauna of freshwater Everglades marshes include the myriad of small fishes, amphibians, reptiles, crayfish, grass shrimp, snails, amphipods and other invertebrates that must play enormously important roles in food webs, nutrient cycles and energy transfers from primary consumers to the highest trophic levels in the ecosystem. Considering their prevalence, little is known about the life histories, population dynamics and ecosystem roles of the aquatic fauna, particularly regarding their ecology in the marl prairies and rocky glades.

Population density of small marsh fishes in the Everglades is directly related to the duration of uninterrupted flooding, and maximum densities are reached only after several years of continual surface water (Loftus and Eklund, 1994; Loftus et al., 1990; Turner et al., 1999 in press). The herpetofauna of the short-hydroperiod wetlands reach higher abundance in habitats with longer hydroperiods and higher water tables (Diffendorfer et al., in preparation.;Dalrymple, 1987; Dalrymple, personal communication). These studies provide evidence that the marl prairies and rocky glades represent stressful environments for aquatic fauna. These marshes typically dried for an average of three months each year under pre-drainage conditions, and extensive areas of this landscape are only wet for an average of three months each year under present conditions (Van Lent et al., 1993; Fennema et al., 1994; VanZee, in preparation). Survival of aquatic fauna during dry periods in the marl marshes and rocky glades depends in the availability of refugia in solution holes, alligator holes, and under periphyton mats which may retain aquatic or moist environments during times when surface water is absent (Loftus et al., 1990; Loftus et al., 1992; Dalrymple, 1987; Diffendorfer et al., in preparation; Loftus, personnal communication; Dalrymple, personal communication).

The small marsh fishes provide the major prey base for the wading birds, wood storks and roseate spoonbills that forage and nest in the Everglades (Ogden, 1994; Bjork and Powell, 1994). Crayfish are particularly important in the diets of white ibis. The marl marshes may provide foraging opportunities for wading birds early in the dry season when deeper water depths in the lower-elevation sloughs are unsuitable for efficient feeding (Fleming, personal communication in Ogden, 1994).

However, the relationship of such foraging opportunities to the advent of nesting and the subsequent reproductive success of wading birds is still hypothetical.

Reduced production and altered species composition of fishes and herpetofauna in the marl prairies and rocky glades result from 1) the direct impact of shortened hydroperiod (Loftus and Eklund, 1994; Turner et al., 1999 in press; Diffendorfer et al., in preparation; Dalrymple, 1987; Dalrymple, personnal communication), 2) indirect impacts of shortened hydroperiod via the loss of the periphyton mat and a reduced primary production food base (Browder et al., 1994), 3) the prolongation of dry conditions and reduction in dry season minimum water levels via the diminished dry season refugium function of solution holes, alligator holes and periphyton mats (Loftus et al., 1992; Diffendorfer et al, in preparation; Dalrymple, 1987; Loftus, personal communication; Dalrymple, personal communication), 4) reduction in spatial extent of wetland habitat (Davis et al. 1994), 5) increased nutrient inputs via the loss of the periphyton mat and a resulting reduction in the primary production food base (Browder et al., 1994), and 6) compartmentalization via levees as potential genetic barriers (Trexler et al., in review) and via canals as corridors for the spread of exotic and higher trophic level fishes (Howard et al., 1995). Measures of aquatic fauna populations that reflect responses to the above stressors include density and species composition of fishes and density of representative herpetofauna and invertebrate species.

American alligator. Prior to drainage, the American alligator was more abundant in the marl marshes and rocky glades than in the deeper central marshes of the Everglades(Craighead, 1968; Mazzotti and Brandt, 1994). By excavating sediments from large solution holes in the limestone bedrock, the alligator created aquatic habitats in which it, and many other groups of aquatic fauna, survived the few months of dry conditions that occurred most years (Craighead, 1968). In the excavation of holes and the creation of nest mounds, the alligator created a micro-topography that supported aquatic as well as terrestrial flora and fauna (Craighead, 1971; Kushlan, 1974). The mounds provided nesting sites not only for the alligator, but also for other marsh reptiles (Deitz and Jackson, 1979; Kushlan and Kushlan, 1980). In these ways, the alligator was a keystone species in the marl prairies and rocky glades because of the aquatic habitats and dry season refugia it created. The high abundance of alligators in the marl marshes and rocky glades, in comparison to lower densities in Shark River Slough, was attributed to high water depths in the Slough that would have been less suitable for alligators prior to drainage (Ogden, 1976; Mazzotti and Brandt, 1994). Given the shortened hydroperiods and lowered water tables in the Everglades due to drainage (Van Lent et al., 1993;Fennema et al., 1994; VanZee, in preparation), the alligator has mostly abandoned the marl marshes and rocky glades, and today the distribution of the alligator in the southern Everglades has shifted to Shark River Slough (Craighead, 1968; Mazzotti and Brandt, 1994). With the loss of alligators from the marl prairies and rocky glades, the habitats and dry season refugia that were provided by its holes and nest mounds have also diminished.

Abandonment by the alligator of the marl prairie/rocky glades has resulted from shortened hydroperiod and increased drought duration and severity, in that the alligator does not occupy habitat that is predominantly dry. Cumulative effects leading to the reduced production of aquatic fauna at all trophic levels probably have also contributed to the demise of the alligator in the mark prairies, since the alligator depends upon these organisms for food during various stages of its life history. The reduced population of alligators has in turn allowed depressions that were previously alligator holes to fill in, further diminishing the populations of aquatic fauna upon which upon which the alligator fed. The restoration of hydroperiods and water tables to those approaching pre-drainage conditions in the marl prairies and rocky glades is anticipated to allow the alligator to re-colonize this region, as measured by <u>density and distribution by age class</u> and <u>density and distribution of alligator holes</u>.

<u>Wading bird and wood stork early dry season foraging</u>. Prior to drainage, the marl prairie/rocky glades may have provided shallow-water foraging opportunities for wading birds and wood storks early in the dry season, at a time when water was too deep to allow successful foraging in Shark River Slough (Fleming, personal communication in Ogden, 1994). The early dry season foraging opportunities may have contributed to the early formation of nesting colonies, and thereby the nesting success of the birds, but this would have been dependent upon an adequate prey base of aquatic fauna in the marl prairie/rocky glades. The relationship of such foraging opportunities to the advent of nesting and subsequent reporductive success of wading birds and wood storks is hypothetical. Under present conditions, both shortened hydroperiod (Van Lent et al.,1993; Fennema et al., 1994; VanZee, in preparation)and loss of spatial extent Davis et al., 1994) have directly reduced the area of feeding habitat and the range of feeding options available to the wading birds and wood storks in the marl prairie/rocky glades (Ogden 1994). Cumulative effects leading to the reduced production of fish and other aquatic fauna, as noted above, have further reduced the prey base for wading birds and wood storks. As a result, the value of the marl prairies and rocky glades for wading bird and wood stork foraging appears to be very limited today in comparison to pre-drainage conditions (Fleming, personal communication in Ogden, 1994) . Measures of wading bird and wood stork utilization of the marl prairie/rocky glades that reflect responses to the above stressors include the <u>seasonal distribution and abundance of foraging birds</u>.

D-A.6.6 HYDROLOGIC PERFORMANCE CRITERIA FOR RESTORATION

Recovery of the ecological values of the marl prairie/rocky glades is dependent upon the reversal of the cumulative effects of decades of drainage, detrimental fire regimes, and exotic plant invasion. The key role of the C&SF Comprehensive plan in the restoration of the marl prairie/rocky glades ecosystem is to provide for the quantity, timing, and distribution of water deliveries that contain low levels of nutrients and toxins. Three priority hydrologic performance measures for the ecological restoration of the marl prairie/rocky glades, in order of priority, are the duration of uninterrupted flooding, drought severity as measured by the duration of dry conditions, and the number of wet season depth reversals.

The duration of a uninterrupted flood events is the highest priority hydrologic performance measure for ecological restoration in the marl prairie/rocky glades. It is identified as the single hydrologic parameter that affects all the ecological values of that region. Only flood events when the mean water depth equals or exceeds 0.2 feet are measured because depths less than 0.2 feet have been observed to impair the establishment of populations of aquatic organisms. The mean duration of all such flood events during the 31-year period of record is the performance measure. The target is the mean duration of flooding indicated by NSM45F. Duration of uninterrupted flooding given a weighting of 3 when averaged with the other performance measures.

Drought severity is the second most important hydrologic variable for ecological restoration in the marl prairie/rocky glades. Drought severity is most clearly indicated by 2X2 model output as the duration of dry conditions. Dry events are defined as times when the water level drops either to zero or a negative value below the ground surface. Two dry events that are separated by a flood event when the water level rises to less than 0.2 feet above the ground surface are grouped as one dry event because such a minor flood event has been observed to not support the establishment of populations of aquatic organisms. In that case, the duration of the dry event is calculated as the sum of the two dry events and the intermittent flood event. The performance measure is the mean duration of all dry events during the 31-year period of record. The target is the mean duration of dry events indicated by NSM45F. The mean duration of dry events is given a weighting of two when averaged with the other performance measures.

Wet season water level reversal is the third most important hydrologic variable for ecological restoration in the marl prairie/rocky glades. A wet season water level reversal is defined as an incident during a period of flooding when water depth recedes to less than 0.2 feet, but then rebounds to greater than 0.2 feet, without the marsh drying completely. A reversal is distinguished from a dry period in that during a reversal, water depth does not drop to or below the ground surface. The performance measure is the total number of reversals during the 31-year period of record. The target is not to exceed the number of reversals indicated by NSM45F.

The number of wet season reversals is given a weighting of one when averaged with the other performance measures.

Ecological values and indicators of restoration success in the rockland marl marsh that are linked to the above hydrologic performance measures in the conceptual model include 1) re-colonization and population resurgence by American alligators and a subsequent increase in the number of occupied alligator holes to serve as dry season refugia for aquatic fauna and to increase habitat heterogeneity, 2) increased population density of aquatic fauna, 3) increased seasonal abundance and foraging activity of wading birds and wood storks, 4) enhanced production and community composition of periphyton, 5) accelerated accretion of marl substrate, 6) increased nesting success and population size of Cape Sable seaside sparrows, and 7) persistence and resilience of highly diverse macrophyte and tree island plant communities.

A performance criterion that is generic to the conceptual models of all physiographic regions of south Florida is the input and bio-accumulation of mercury and other toxins. Potential inputs of mercury and pesticides in agricultural and urban runoff water that may be needed for hydropattern restoration in the marl prairie/rocky glades might result in reduced health, behavioral and physical abnormalities, and loss of reproductive vigor of the fauna unless measures are taken to restrict loads of these toxins in inflow water. Measures of faunal health that reflect responses to the mercury and pesticide inputs include body burdens of mercury and other toxins in representative species of fauna and the incidence of physical and behavioral abnormalities in fauna.

D-A.7 DRAFT MANGROVE ESTUARY TRANSITION CONCEPTUAL MODEL

D-A.7.1 PREPARER

Steven M. Davis, South Florida Water Management District, West Palm Beach, Fl.

D-A.7.2 INTRODUCTION

A brackish water ecotone of coastal bays and lakes, mangrove and buttonwood forests, salt marshes, and tidal creeks separates Florida Bay from the freshwater Everglades. The 24 km-wide ecotone adjoins the north shoreline of Florida Bay between Highway Creek (US1) and Whitewater Bay, which delineate the eastern and western boundaries of the mangrove estuary transition model. Whitewater Bay is included in the model because it is influenced by the Shark River drainage basin originating in the Everglades. The mangrove estuary transition is characterized by a salinity gradient and mosaic that vary spatially with topography and that vary seasonally and inter-annually with rainfall and freshwater flow from the Everglades. Because of its location at the lower end of the Everglades drainage basin, the mangrove estuary transition zone is potentially affected by upstream water management practices that alter the freshwater heads and flows that drive salinity gradients.

D-A.7.3 ECOLOGICAL STRESSORS

Stressors on the mangrove estuary transition ecosystem and the drivers that create them fall into five categories (refer to figures on pages D-A-87& 88). Sea level rise is an important non-societal driver (Wanless et al., 1994) that is causing the inland movement of marine conditions into the estuary transition zone (Meeder et al., 1996). The inland movement of marine conditions due to sea level rise is happening independent from other societal-driven stressors. The societal-driven water management operations of the C&SF Project stress the transition zone through reductions in the volume and duration of freshwater flow entering the zone (McIvor et al., 1994) The introductions of exotic fishes and plants are other societal-driven drivers that have resulted in the dominance of the Mayan cichlid east of Taylor Slough (Trexler et al., in prep.) and the invasion of *Schinus* and *Colubrina* into mangrove forests (Armentano et al., 1995). The societal input and bioaccumulation of mercury and other toxins pose a threat to faunal health at all trophic levels in all south Florida ecosystems, including the mangrove estuary transition, as discussed under generic issues.

D-A.7.4 ECOLOGICAL EFFECTS: CRITICAL LINKAGES BETWEEN STRESSORS AND ECOLOGICAL VALUES

The inland movement of marine conditions due to sea level rise and the reduced input of freshwater due to water management work together to alter and compress the salinity gradient of the mangrove estuary transition (Browder and Moore, 1981). They both result in the landward movement of salinity, the loss of a seasonal shift from moderate saline to oligohaline conditions, and occurrence of hypersalinity within the transition zone during dry years. Both directly change habitat structure by contributing to the siltation and mangrove encroachment of tidal creeks (Meeder et al., 1996), to the extent that open water courses that were described earlier this century are no longer recognizable (Glen Simmons, personal communication).

The alteration and compression of the salinity gradient results in the loss of the spatial overlap of salinity zones with shoreline habitat and nursery grounds (Browder and Moore, 1981). Ecological values of the mangrove estuary transition that depend on the overlap of salinity and habitat include the mangrove/salt marsh vegetation mosaic, the resident mangrove fish assemblage, the wood stork and roseate spoonbill, the American crocodile, spotted seatrout nursery grounds, pink shrimp nursery grounds, and coastal lake vegetation and waterfowl.

D-A.7.5 ECOLOGICAL VALUES / ATTRIBUTES AND MEASURES

Mangrove/salt marsh vegetation mosaic. The alteration and compression of the salinity gradient potentially can affect the community cover, distribution, and production of the mangrove forests (*Rhizophora*, *Avicennia*, *Laguncularia*, and *Conocarpus*), salt marshes and tidal creeks of the mangrove estuary transition that are documented by Welsh et al. (1995). Some mangrove forests in the transition zone have experienced invasion by the exotic trees *Schinus* and *Colubrina* (Armentano et al., 1995). Tidal creeks and adjacent salt marshes have been encroached by red mangrove as described above. The invasion of the freshwater marl marshes at the upstream end of the salinity gradient by red mangrove (Meeder et al., 1996) corresponds to an accelerated rate of sea level rise The vegetation mosaic defines the habitats of the mangrove estuary transition zone. The spatial distribution of those habitats, in combination with the salinity gradient that overlays them, may determine the suitability of this region to sustain its ecological values (Browder and Moore, 1981). The importance of this habitat mosaic warrants the monitoring of the distribution and cover of vegetation communities and tidal creeks in the mangrove estuary transition zone as efforts proceed to restore freshwater inputs and salinity regimes.

Resident mangrove fish community. The resident fish community of sheepshead, sailfin mollies, topminnows, rainwater killifish, and sunfish thrives under low salinity, decreasing in production and increasing in mortality when salinity exceeds 5-8 ppt (Lorenz, 1997 and in press). The exotic Mayan cichlid has become established in this fish community to the extent that it presently is the dominant species from Taylor River east to Highway Creek (Trexler et al., in prep.). Lowered salinity regimes due to increased freshwater inputs are expected to result in community recovery as measured by increased production and abundance of resident mangrove fishes. The dependence of wood storks on larger resident mangrove fishes above approximately 10 cm in length (Ogden et al., 1978) provides an additional measure of increased survival of topminnows and sunfish to year class one (into their second year of life). Consistently lower salinities at the upstream end of the salinity zonation are expected to reduce mortality and allow survivorship of these species to the larger size classes that are available to wood storks.

Wood stork and roseate spoonbill. The collapse of the coastal nesting colonies of wood storks and great egrets is attributed largely to a decline in the production and density of the resident mangrove fishes (Ogden, 1994), particularly topminnows and sunfish that survive past their first year to a size that wood storks can capture (Ogden et al., 1978). The decline in roseate spoonbill nesting and the shift of nesting distribution from eastern to western Florida Bay (Powell et al., 1989) are also attributed to the reduction in populations of resident mangrove fishes upon which they feed (Bjork and Powell, 1994). Small fishes have been reported to be the primary part of the diet of roseate spoonbills in Florida Bay (Allen, 1942; Powell and Bjork, 1990). Increased density of resident mangrove fishes and increased fish survival to year class one, as a result of consistently lower salinity patterns at the upstream end of the gradient, are expected to contribute to the re-establishment of wood stork coastal nesting colonies, the re-establishment of roseate spoonbill Florida Bay nesting colonies east of Seven Palm Lake, and an increase in number of nesting pairs and nesting success of both species.

American crocodile. The American crocodile dwells in the ponds and creeks of the mangrove estuaries of Florida Bay (Ogden, 1976; Mazzotti, 1983). American crocodiles are tolerant of a wide salinity range as adults because of their ability to osmoregulate (Mazzotti, 1989). Juvenile crocodiles lack this ability, however, (Mazzotti, 1989) and their growth and survival decline at salinities exceeding 20 ppt (Mazzotti et al., 1988; Mazzotti and Dunson, 1984; Moler, 1991). Juvenile crocodiles tend to seek freshwater pockets such as black mangrove stands when those choices are available. Re-establishment of a salinity gradient with levels below 20 ppt in shoreline and tidal creek habitats, which would indicate a gradient and mosaic of lower salinities upstream, is expected to benefit the crocodile as measured by increased growth and survival of juveniles.

Spotted seatrout nursery grounds. Post larval spotted seatrout utilize the coastal basins of the Florida Bay mangrove estuary as nursery grounds from Terrapin Bay west to Whitewater Bay. Densities of post larvae in those basins are highest at an intermediate salinity range of 20-30 ppt, and densities drop when salinity exceeds that of seawater (35 ppt) (Thayer et al., 1998; Schmidt, 1993). Restoration of a salinity gradient with a persistent zone of <35 ppt in the coastal basins, as a result of freshwater input from upstream, is expected to result in an increase in the post larval density and thereby an enhancement of the nursery ground value for spotted seatrout and possibly other sport fish species in the coastal basins.

Pink shrimp. Mangrove estuaries in Everglades National Park, along with Florida Bay, are nursery grounds for pink shrimp, an ecologically and economically important species in south Florida. Pink shrimp are harvested commercially on the Tortugas grounds, and the pink shrimp fishery is one of south Florida's most valuable fisheries in terms of ex-vessel value. Pink shrimp are also a food source for many recreationally and commercially important estuarine and marine species such as mangrove snapper and spotted seatrout (Higher Trophic Levels Working Group, 1998).

Pink Shrimp spawning occurs in the Dry Tortugas area, and eggs and larvae are carried inshore by currents and tides (Jones et al., 1970; Hughes, 1969). Browder (1985) and Sheridan (1996) have found positive relationships between indices of freshwater inflow to the coast and Tortugas pink shrimp landings. Sheridan's annually updated statistical model based on various freshwater inflow indices has successfully predicted annual pink shrimp landings in most of the past decade (Sheridan 1996 and unpublished). The salinity gradient associated with coastal runoff may provide navigational directions to immigrating young pink shrimp (Hughes, 1969). Survival rates of juvenile pink shrimp are sensitive to salinity and decrease markedly under extreme hypersaline conditions (Browder, in press). Optimal salinities for survival are not fully determined, but probably are somewhat below that of seawater (35 ppt). Tabb et al. (1962), Rice (1997), and others have documented that the mangrove estuaries in the Whitewater Bay system of Everglades National Park are pink shrimp nursery grounds.

Coastal lake vegetation and waterfowl. Compression of the salinity gradient has changed the coastal lakes and basins of the mangrove ecotone from estuarine to predominantly marine systems. Coastal lakes such as Seven Palm Lake, Cuthburt Lake, Long Lake, West Lake, Lake Monroe and the Taylor River ponds are contained within the mangrove forest and are connected to Florida Bay only by tidal creeks. Coastal basins such as Joe Bay, Little Madeira Bay, Terrapin Bay, Garfield Bight,and Whitewater Bay open directly to Florida Bay or the Gulf of Mexico. The coastal lake and basin estuary ecosystems require seasonal salinity variations from oligohaline (wet season) to mesohaline (dry season) conditions, in contrast to the mesohaline to marine conditions that presently occur during most years. Prolonged periods of salinity concentrations near that of seawater (35 ppt) in the coastal lakes and basins appear to have contributed to the near-elimination the once-abundant beds of the submerged aquatic plants *Ruppia*, *Chara*, and *Utricularia* (Ogden, personnal communication) which require oligohaline to mesohaline conditions (Morrison and Bean, 1997). *Utricularia* tolerates only oligohaline salinities with an upper limit of 5-8 ppt. *Chara* also thrives under freshwater conditions but tolerates mesohaline salinities up to 15-20 ppt. *Ruppia* grows under a mesohaline salinity range of 10-25 ppt. Waterfowl species including coot, scaup, widgeon and pintail feed on the *Ruppia*, *Chara*, and *Utricularia*. The reduction in beds of these plants apparently has contributed to the precipitous decline in numbers of seasonally abundant waterfowl that formerly utilized the coastal lakes and basins (Kushlan et al., 1982). Recent high-rainfall years have witnessed an increase in coot numbers on the West Lake to approximately 2000 during winter 96-97 (Bass, personal communication), but not to the population size of approximately 50,000 that over-wintered there until the 1960's (Kushlan et al., 1982). Re-establishment of a salinity gradient that restores seasonal variation from oligohaline to mesohaline conditions in the coastal lakes and basins is expected to result in an increase in the aerial cover of *Ruppia*, *Chara*, and *Utricularia* and the return of winter waterfowl populations of coot, scaup, widgeon and pintail to the lakes and basins.

D-A.7.6 HYDROLOGIC PERFORMANCE CRITERIA FOR RESTORATION

Ecological restoration of the mangrove estuary transition requires a reduction in the frequency of high salinity events that have been identified for each coastal basin through the conceptual model process. Another restoration criterion is to increase the frequency of low salinity events that have been identified for each coastal basin. The high and low salinity levels represent the best professional judgement of those scientists working in the mangrove estuary, based on the existing information on the biological requirements and distributions of the estuarine organisms that are described above, available salinity data, and field observation.

Table 1 displays the lower and upper salinity levels identified for coastal basins. It is desirable to decrease the frequency that salinity exceeds upper levels, and to increase the frequency that salinity drops below lower levels.

Table 1
Salinity Values

Basin	Lower Level	Upper Level
Joe bay	5 ppt	15 ppt
Little Madeira Bay	15 ppt	25 ppt
Terrapin Bay	25 ppt	35 ppt
Garfield Bight	25 ppt	35 ppt
North River Mouth	5 ppt	15 ppt

The strategy for ecological restoration of the mangrove estuary transition is to maintain freshwater heads and flows in the Everglades at the upstream end of the salinity gradient in order to achieve desirable salinity regimes in the Florida Bay coastal basins at the downstream end of the salinity gradient. Regression analyses demonstrated inverse relationships of salinity in the coastal basins to water level upstream in the Everglades (Davis, 1997). The regressions indicated that stages of 7.3 and 6.3 feet msl at the P33 gage in central Shark River Slough produce the lower and upper salinity levels for Joe Bay, Little Madeira Bay, Terrapin Bay, Garfield Bight, and North River Mouth. Four performance measures for the ecological restoration of the Florida Bay mangrove estuary and coastal basins are derived from the simulated stages at the P33 gage and salinity levels in the coastal basins.

The frequency of stages of 6.3+ at P33 is applied as a performance measure for the Florida Bay coastal basins. The performance measure is the number of months during the 31-year period of record when stages at P33 rose to, or above, 6.3. The target is the number of months that NSM45F provided stages of 6.3 or above. A reduced frequency of high salinity events is given a high priority in the ecological restoration of the coastal basins, thus the frequency of 6.3+ stages is given a weighting of two when averaged with the other performance measures.

The frequency of stages of 7.3+ at P33 is applied as a performance measure to the Florida Bay coastal basins. The performance measure is the number of months during the 31-year period of record when stages at P33 rose to, or above, 7.3. The target is the number of months that NSM45F provided stages of 7.3 or above. An increased frequency of low salinity events is given a lower priority than a reduced frequency of high events, thus the frequency of 7.3+ stages is given a weighting of one when averaged with the other performance measures for the coastal basins.

The transition from the late dry season to the early wet season during March through June is a critical period to estuarine organisms in the Florida Bay coastal basins regarding the frequency and duration of high salinity events. Salinity is estimated based on relationships between mean monthly salinity in the coastal basins and water stage at the P33 gage in mid Shark River Slough. The cumulative salinity difference (ppt) from the high salinity levels that have been identified for Florida Bay coastal basins is summed during the dry/wet season transition months of March-June. Differences are summed over five coastal basins (Joe Bay, Little Madeira Bay, Terrapin Bay, Garfield Bight and North River Mouth) and over the 31-year period of record. Differences above the specified high salinity levels are given a positive value, and differences below the high salinity levels are given a negative value. The target is to reduce the cumulative salinity difference to a value that does not exceed the cumulative difference produced by NSM45F. The cumulative March-June salinity difference from high levels is given a weighting of one when averaged with the other performance measures for the coastal basins

During the August-October transition from the late wet season to the early dry season, it is important to achieve low salinity levels in the Florida Bay coastal basins to provide the seasonal environment for low-salinity estuarine organisms and to postpone the onset of high salinity events further into the dry season. Salinity is estimated based on relationships between mean monthly salinity in the coastal basins and water stage at the P33 gage in mid Shark River Slough. The cumulative salinity difference (ppt) from the low salinity levels that have been identified for the Florida Bay coastal basins is summed during the wet/dry season transition months of August-October. Differences are summed over the five coastal basins and over the 31-year period of record. Differences above the specified low salinity levels are given a positive value, and differences below the low salinity levels are given a negative value. The target is to reduce the cumulative salinity difference to a value that does not exceed the cumulative difference produced by NSM45F. The cumulative August-October salinity difference is given a weighting of one when averaged with the other performance measures for the coastal basins.

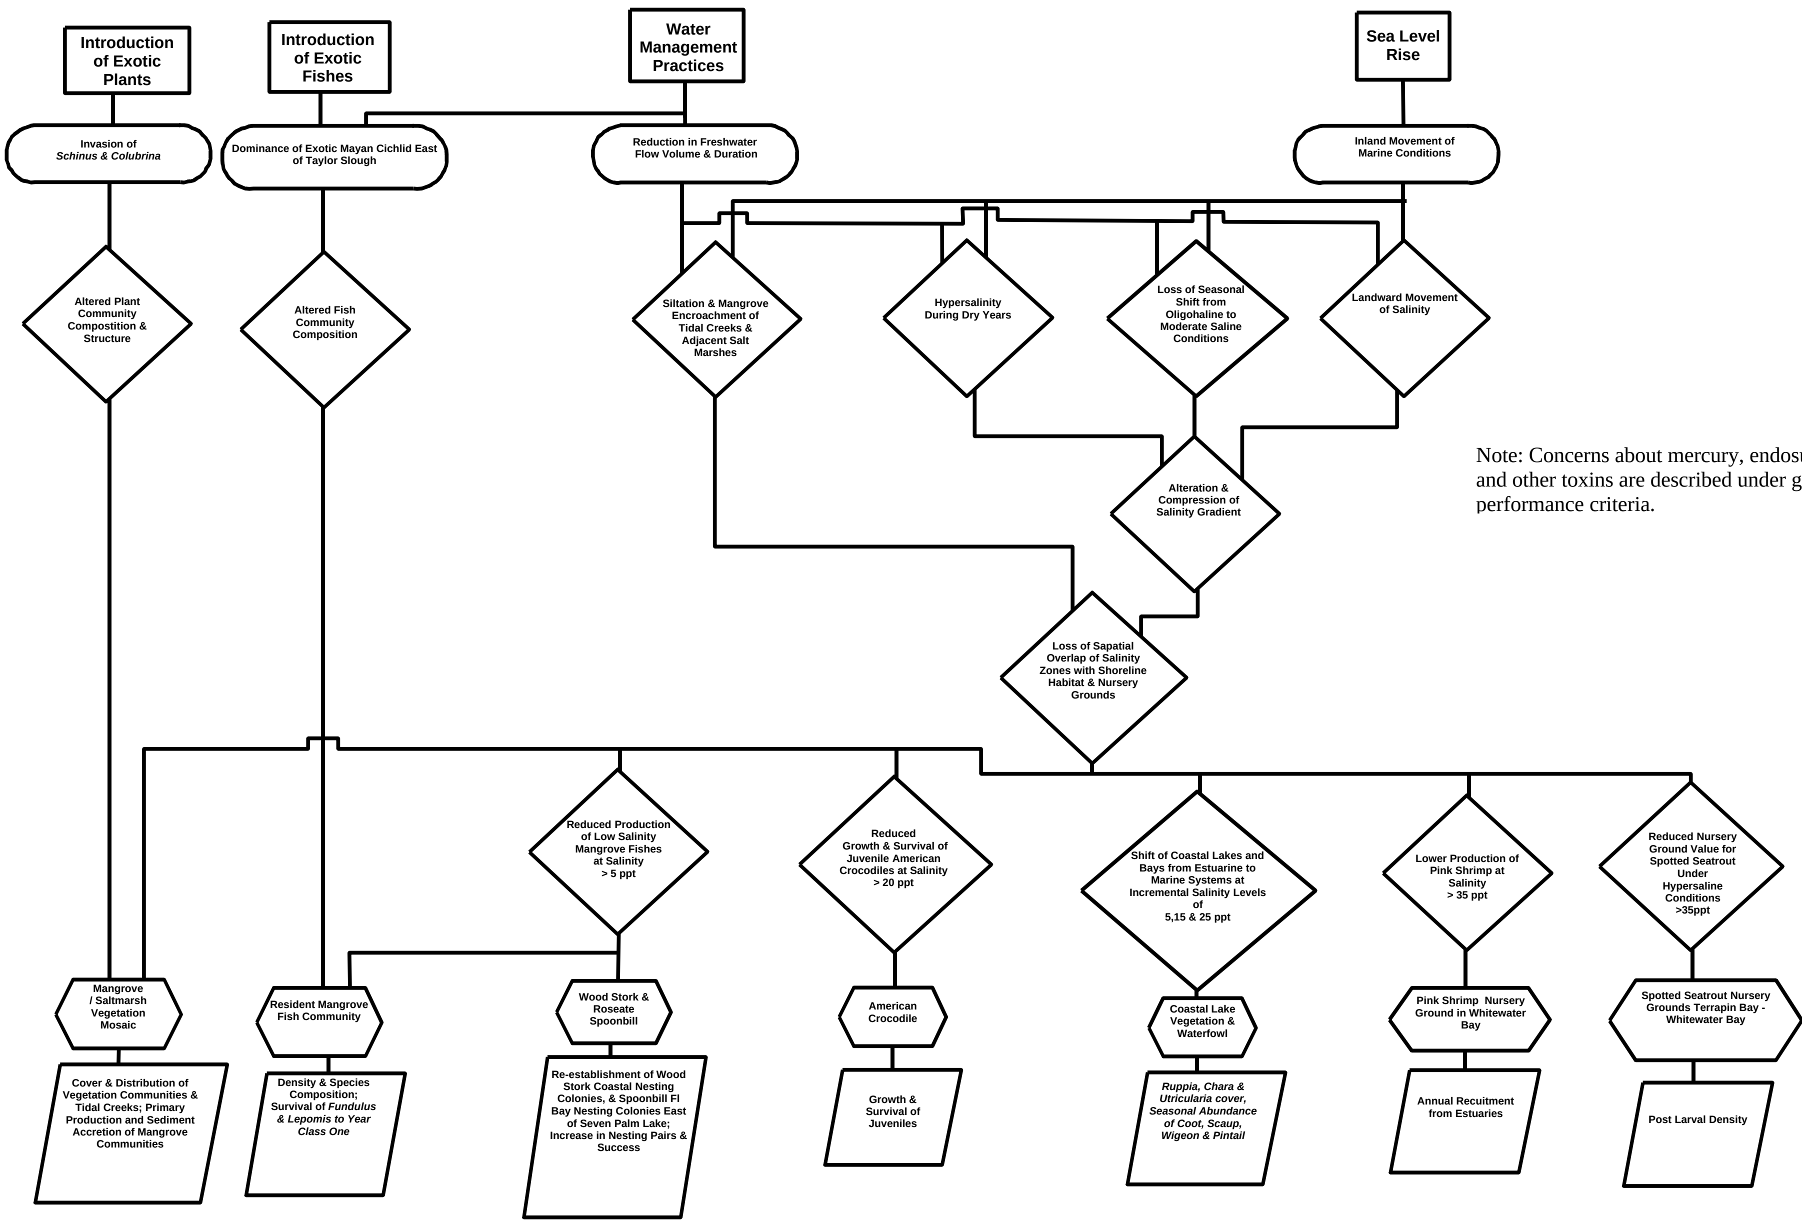
Ecological values and indicators of restoration success in the Florida Bay mangrove estuary and coastal basins that are linked to the above hydrology/salinity performance measures in the conceptual model include 1) increased production of low-salinity mangrove fishes, 2) re-establishment of coastal nesting colonies of wood storks/great egrets and eastern Florida Bay colonies of roseate spoonbill, 3) earlier timing of coastal colony formation by wood storks/great egrets and of Florida Bay colony formation by roseate spoonbills, 4) increased growth and survival of juvenile American crocodiles, 5) increased cover of low-to-moderate salinity aquatic macrophyte communities in coastal lakes and basins, 6) return of seasonal waterfowl aggregations to coastal lakes and basins, 7) enhanced nursery ground value for spotted seatrout and pink shrimp in coastal basins, and 8) persistence and resilience of the mangrove, salt marsh and tidal creek vegetation mosaic.

A performance criterion that is generic to the conceptual models of all physiographic regions of south Florida is the input and bio-accumulation of mercury and other toxins. Potential inputs of mercury and pesticides in agricultural and urban runoff water that may be needed for freshwater input into the mangrove estuary transition might result in reduced health, behavioral and physical abnormalities, and loss of reproductive vigor of the fauna unless measures are taken to restrict loads of these toxins in inflow water. Measures of faunal health that reflect responses to mercury and pesticide inputs include body burdens and the incidence of physical and behavioral abnormalities in representative species.

D-A.7.7 MOVING TARGET

Predicted rises in sea level require re-evaluation of relationships between Everglades stage and mangrove estuary transition salinity during the next century. However, the strategy for the maintenance of salinity at the lower end of the gradient by adjusting upstream water stage at key Everglades gages will continue to apply. Maintaining Everglades stages based on presently derived stage/salinity relationships provides one potential strategy to support a salinity gradient, but with a landward shift in response to rising sea level. Raising Everglades stages based upon revised stage/salinity relationships provides another potential strategy to offset sea level rise and maintain the mangrove estuary transition in its present location. Regardless of rising sea level, however, a salinity gradient supportive of an ecologically functional mangrove estuary transition zone will be required to maintain the integrity of the south Florida ecosystem.

Mangrove Estuary Transition Conceptual Model (Feb 99)



Note: Concerns about mercury, endosulfan and other toxins are described under generic performance criteria.

D-A.8 DRAFT BISCAYNE BAY CONCEPTUAL ECOLOGICAL MODEL

D-A.8.1 PREPARERS

Diego Lirman, Elizabeth A. Irlandi, and Wendell P. Cropper, Jr., Center for Marine and Environmental Analyses, University of Miami, Miami, Florida.

D-A.8.2 INTRODUCTION

Biscayne Bay is a subtropical lagoon located on the southeast coast of Florida. The Bay is generally subdivided into three sections with unique biological and physical characteristics: a) North Bay, north of the Rickenbacker Causeway, b) Central Bay, from the Rickenbacker Causeway to Card Sound, and 3) South Bay, an area that includes Card Sound and Barnes Sound (VanArman et al., 1989).

The North Bay, an area heavily influenced by urban development activities, has reduced water clarity, high concentrations of toxicants and nutrients, and chronic sewage pollution (e.g., Wanless, 1976; Harlem, 1979; Judge et al., 1979; Wanless et al., 1984; Corcoran et al., 1987). The main sources of pollution for this heavily urbanized watershed are the Miami River, the Port of Miami, and various canals (e.g., Buck, 1976; Corcoran et al., 1984; Dade County , 1987; Markley et al., 1990). High levels of toxic metals, organic contaminants and pesticides have been found in the water and sediments of discharge sites. Altered salinity regimes, increased nutrient and contaminant loadings, and high water turbidity have all contributed to the decreased health and extent of biological communities within the northern section of Biscayne Bay.

The central portion of the Bay is better flushed than the North Bay and has extensive, healthy seagrass beds and other benthic communities. Nevertheless, industrial and agricultural discharges, as well as leachete from the South Dade landfill, are important sources of pollution to this area (McKenzie, 1983; Shinn and Corcoran, 1987). A salinity gradient is found in the Central Bay, with lower, variable salinity occurring on the western margin of the Bay due to freshwater inflow from canal discharge and runoff, and higher, more stable salinities in the eastern margin, where oceanic influences prevail (Wang et al., 1978; Chin Fatt and Wang, 1987).

The southern portion of the Bay (Card Sound and Barnes Sound) is influenced primarily by agricultural development. Freshwater inflow into the area is mostly through canal discharge, and flushing is limited as there are no direct connections to the ocean. Accordingly, salinity can vary from relatively low values during the wet season (10-20 ppt) to potentially hypersaline values (40-45 ppt.) during the dry season (Lee and Rooth, 1975). Southern Biscayne Bay has extensive, healthy seagrass beds, and is critical habitat for a number of threatened species such as the Cape Sable seaside sparrow, roseate spoonbills, as well as crocodiles, manatees, and snail kites (Kushlan and White, 1977; Kushlan and Mazzotti, 1989).

The benthic habitats of Biscayne Bay are dominated by extensive beds of seagrass that cover most of the Bay bottom (Thorhaug, 1976). *Thalassia testudinum* is the dominant seagrass species, but *Halodule wrightii* and *Syringodium filiforme* are also present and may dominate locally. The seagrass beds also have associated rhizophytic (e.g., *Halimeda* spp., *Penicillus* spp., *and Udotea* spp.) and drift-algal (e.g., *Laurencia* spp., *Polysiphonia* spp.) components. Hardbottom areas with sponges, soft corals, hard corals, and macroalgae are less extensive and occur primarily in the eastern and central portions of the Bay (DiResta et al., 1995; Cropper and DiResta, 1999).

Both commercial and recreational fishing are important activities within Biscayne Bay (Berkeley et al., 1985). Sport-fishing activities are concentrated mainly on fish species such as tarpon, snook, bonefish, and permit (deSylva, 1969). The groups of organisms harvested commercially within the Bay include: spotted seatrout, the snapper-grouper fish complex, bait fish, bait shrimp, stone and blue crabs, lobsters and sponges (Ault et al., 1997).

D-A.8.3 DRIVERS AND STESSORS

The anthropogenic and natural drivers creating potential stressors to the Biscayne Bay ecosystem include urban, industrial, and agricultural development, water management (C&SF project), commercial and recreational fishing and boating activities, and natural disturbances such as storms (refer to figure on page D-A-99).

Prior to the extensive human development in the area, inputs of fresh water into Biscayne Bay were mainly from the Miami River, Little River, Arch Creek, and Snapper Creek. Sheet flow from the adjacent Everglades system, artesian flow from the underlying limestone bedrock, and runoff after storms or heavy rains were important additional sources of fresh water before development (Harlem, 1979; Wanless et al., 1984).

However, since the early 1900s, the hydrology of the Bay has been significantly modified due to coastal construction and the development of the extensive water management system now in place (Wanless et al., 1984). Fresh water input patterns have been highly modified from pre-development patterns, limiting both surface and groundwater inflow into the Bay. At present, the main sources of fresh water are local rainfall and runoff, as well as canal discharges (Wanless et al., 1984).

During the rainy season, tremendous volumes of water can be released through flood control structures creating large and rapid fluctuations in salinity in the vicinity of canal mouths and over-all reduced salinity on the western fringe of the Bay (Wang et al., 1978). Increases in freshwater inflow from runoff as well as from point sources have also contributed to a significant decrease in water quality within Biscayne Bay. Major issues of concern include increased sedimentation and turbidity as well as increased nutrient loading and chemical pollution (VanArman et al., 1989).

Both commercial and recreational boating activities can cause significant physical damage to seagrass beds, hardbottom communities, and manatees (O'Shea et al., 1985; Sargent et al., 1995; Ault et al., 1997). Major storms can also have significant effects on water quality and benthic habitats. After Hurricane Andrew, high turbidity, increased nutrient and pollutant loading, high dissolved organic carbon, and persistent plankton blooms were observed within Biscayne Bay (Tilmant et al., 1994). Benthic communities also experienced high erosion, and burial and removal of organisms during Andrew and previous hurricanes (Thomas et al., 1962; Tilmant et al., 1994).

D-A.8.4 EFFECTS

<u>Salinity</u>: Alterations in salinity can impact species composition and productivity of seagrass communities. Of the three most abundant seagrass species that occur in the Bay, *Halodule* is the most tolerant of low-salinities, and tends to be dominant in areas adjacent to canal discharge sites. *Thalassia* and *Syringodium* are also found near canals, but growth and productivity of these species is reduced at sites influenced by freshwater discharge (Conover, 1964; Lewis et al., 1985; Montague, 1989). Salinity also affects other benthic primary producers associated with seagrass communities. Pulses of reduced-salinity water can have negative effects on the growth of the drift alga *Laurencia* and rhizophytic algae such as *Penicillus* spp., *Udotea* spp., and *Halimeda* spp. (Conover, 1964; Irlandi et al., unpublished data).

Similarly, salinity fluctuations can affect faunal composition and abundance as some species are more tolerant to low salinity than others (Serafy et al., 1997). Salinity effects on the distribution of grazers (both fish and invertebrate) may influence the abundance of phytoplankton, epiphytes and macroalgae that can potentially shade seagrasses (Irlandi et al., 1997). Negative effects of low salinity have also been detected in sponges (Smith, 1973; Storr, 1976).

<u>Pollution</u>: Urban and agricultural development, as well as boating activities in the Bay, contribute to the introduction of contaminants and toxins into the environment. The use of herbicides in farming may potentially influence seagrass growth and production while heavy metals, mercury, and other toxic materials can be detrimental to the health and survival of fish populations and higher trophic levels that feed on them (e.g. bioaccumulation of toxins). Several studies have detected a high number of abnormalities in several fish species within Biscayne Bay, specially around heavily polluted areas such as marinas and canal outflows (e.g., Browder et al., 1993; Gassman et al., 1994)

<u>Nutrients</u>: Agricultural runoff, urban runoff, and stormwater release can result in an increase in both water-column and sediment nutrients, promoting growth of

phytoplankton, seagrass epiphytes, and macroalgae (e.g., Lapointe and Clark, 1992; Frankovich and Fourqurean, 1997). Phytoplankton blooms, epiphyte growth, and growth of attached and drift macroalgae can reduce light availability to seagrasses and reduce their growth and production. Similarly, high concentrations of phytoplankton may be deleterious to filter-feeding sponges in hardbottom habitats due to a potential clogging effect.

Nutrient gradients caused by point sources may have a major influence on the abundance, composition, and distribution of benthic communities. Mats of drift algae are common along the western boundary of the Bay where several canals drain agricultural fields, and their growth and distribution may be the direct result of the increased nutrients. Changes in nutrient levels can also affect the community composition of seagrass meadows by influencing the competitive interactions among the dominant seagrass species (Williams, 1987; Harwell and Fong, 1994; Fong et al., 1997), producing shifts in dominance from *Thalassia* to *Halodule* (Fourqurean et al., 1995) as well as influencing competitive interactions between seagrasses and algae (Williams, 1990; Holmquist, 1992).

Sedimentation: Increased sediment loads associated with canal discharge, runoff, and resuspension due to storms and boating activities can increase water turbidity, shading benthic plants and decreasing productivity (Hall et al., 1991; Onuf, 1991; Tilmant et al., 1994; Sargent et al., 1995). If sediment concentrations are high, there is also the potential for burial and smothering of benthic-communities components.

Harvesting and Poaching: Commercial and recreational fishing can influence the biotic communities of Biscayne Bay. Fishing pressure, species targeted, and size of fish captured can alter the species composition and trophic structure of fish communities. For example, the removal of omnivorous bait fish in large quantities (e.g., pinfish) may result in decreased grazing rates that may facilitate algal and epiphyte overgrowth of seagrasses and hardbottom-community components.

Poaching can also have significant impacts on the populations targeted. The removal of undersized lobsters as well as the removal of large, reproductive sponges can have significant long-term effects on the survival of these populations (Cropper and DiResta, 1999).

Many of the commercially and recreationally important fish and macroinvertebrates found in the Bay rely on seagrass and hardbottom habitats for food and/or shelter, therefore, factors influencing the distribution, productivity, and abundance of these benthic habitats will have an effect on the distribution and abundance of fishery resources in the Bay.

Physical Damage: Direct physical damage to the biotic communities of Biscayne Bay can be caused by boating and harvesting activities as well as by intense storms.

Shrimp trawlers actively target seagrass habitats but may venture into hardbottom areas removing and damaging sponges and gorgonians with their gear. Ault et al. (1997) found that considerable damage to both seagrass and hardbottom communities can result from trawl and trap fishing practices. Significant by-catch of juvenile fish that suffer physical damage and/or mortality can also occur.

Most of the seagrass beds within Biscayne bay show some signs of boat scarring. Boat scars result in the loss of essential habitat for associated fauna, sediment erosion, and increased water turbidity (Sargent et al., 1995). Furthermore, several studies have shown that the recovery of deep scars by seagrasses can be a slow process taking anywhere from a few months to several years to recuperate original seagrass shoot densities (Zieman, 1976; Durako et al., 1992). Lastly, the scouring effects of sediments suspended during intense storms may cause significant mortality of benthic organisms and affect their distribution within the Bay (Tedesco et al., 1995).

D-A.8.5 ATTRIBUTES AND MEASURES

A set of endpoints or attributes can serve as indicators of the health of the Biscayne Bay ecosystem. Most of these attributes are biological components of the system such as the health of birds, macroinvertebrates (e.g., lobsters, shrimp, scallops), fishes, manatees, and seagrass and hardbottom communities.

<u>Faunal Communities</u>: This endpoint considers the abundance, size, and health of Bay species or species groups that are of commercial or recreational importance such as bait shrimp, crabs, lobsters, tarpons, bonefish, snappers and groupers, birds, dolphins, crocodiles and manatees. Measurements and indicators for this endpoint include distribution, abundance, growth, recruitment, and population size structure of these organisms, nest distribution, as well as incidence of disease and abnormalities. Information about the health of commercial stocks could be obtained from landings and fishing effort statistics.

<u>Seagrass Communities:</u> Seagrasses compose a keystone community within Biscayne Bay; they not only dominate spatially but also serve as essential habitat (e.g., food and refuge) for a productive food web. Their presence also plays a role in maintaining water quality (e.g., sediment stabilization, nutrient uptake), another major endpoint for the Bay. The spatial extent, density, and productivity of seagrass beds are key attributes of these communities and can be estimated directly.

<u>Hardbottom Communities:</u> Hardbottom communities within Biscayne Bay contain high densities of sponges, soft corals, and macroalgae. Hard corals can also be important components locally. Just like seagrass communities, hardbottom communities provide essential habitat for a large number of organisms. Juvenile lobsters are often found within sponges (Butler et al., 1994) and large stands of the attached alga *Sargassum* provide both food and shelter to juvenile fishes seasonally.

Also, water and sediment quality are important attributes of the system as the health of the biological components is often tightly linked to them. Direct indicators and measurements of water and sediment quality include turbidity, salinity, dissolved oxygen, bacterial counts, chlorophyll concentrations, and the concentration of nutrients and pollutants. Secondary indicators of reduced water and sediment quality may be the distribution and composition of invertebrate communities (e.g., meiofauna) that respond differently to different environmental conditions.

D-A.9.2 INTRODUCTION

A simple conceptual model of the Florida Bay ecosystem is presented here. This model is consistent with our effort to assess the current understanding of south Florida's ecosystems, identify the most important human effects on these ecosystems, identify restoration goals and success criteria, and identify the minimum measurements required to determine whether these criteria are being met. The structure of the model is largely based on the expert opinions of scientists who have focused their attention on Florida Bay during the past several years. During this time, detailed reviews of our understanding of the Florida Bay have been presented (Boesch et al. 1993, Boesch et al. 1995, Boesch et al. 1997, Fourqurean and Robblee 1999). Detailed plans that identify quantitative information needs for environmental management decision making, as well as strategies to provide this information, have also been presented (Armentano et al. 1994, Armentano et al. 1997). While the conceptual model presented here is largely consistent with the body of knowledge described in the reviews and plans noted above, some details or omissions of this model may not be consistent will the opinions of every contributor listed above or every contributor to the larger Florida Bay research effort.

Florida Bay primer. Florida Bay is a triangularly shaped estuary, with an area of about 850 square miles, that lies between the southern tip of the Florida mainland and the Florida Keys. About 80% of this estuary is within the boundaries of Everglades National Park. A defining feature of the bay is it's shallow depth, with a mean depth of about 1 meter (Schomer and Drew 1981). This shallowness allows light to penetrate through the water to the sediment surface in almost all areas of the bay and results in the potential for the bay to sustain seagrass beds as a dominant habitat and source of productivity. The shallowness of the bay also affects the circulation and salinity regime of the bay; with a complex network of shallow mud banks, water exchange among the bay's basins and between these basins and the Gulf of Mexico is restricted (Smith 1994, Wang et al. 1994). With a long residence time and shallow depth, the salinity of Florida Bay water can rapidly rise during drought periods. Salinity levels as high as twice that of seawater have been measured (McIvor et al. 1994). Another defining feature of the bay is that the sediments are primarily composed of carbonate mud, which can scavenge inorganic phosphorus from bay waters (DeKanel and Morse 1978).

Until the 1980s, Florida Bay was perceived by the public and environmental managers as being a healthy estuary, with clear water, lush seagrass beds, and productive fish and shrimp populations. By the mid 1980s, however, catches of pink shrimp had declined dramatically (Browder et al. 1999) and in 1987, the mass mortality of turtle grass (Thalassia) beds began (Robblee et al. 1991). By 1992, the ecosystem appeared to shift from a clear water system, dominated by primary production on the sediment (benthic production) to a turbid water system, dominated by algae blooms in the water column and resuspended sediment. The conceptual model focuses on these changes in seagrasses and water quality as the central issues to be considered by environmental managers.

Reality check. The simple model presented below does not address the spatial complexity of Florida Bay. Florida Bay is, indeed, not so much a singular estuary, but a complex array of basins, banks, and islands that differ across a set of regions. The mosaic of seagrass habitat and mangrove habitat, as well as water quality and ecosystem processes, vary distinctly with this spatial variation. Nevertheless, only a single, generic model is described and this model is intended to summarize the main characteristics and trends of the bay. While the structure of this model is appropriate for most areas of the bay, the relative importance of the model's components differ considerably among the bay's sub-regions. Any application of this model (for example, recommendations for a specific set of monitoring parameters and guidelines) must take the spatial variability of the bay into account.

D-A.9.3 STRESSORS AND SOURCES OF STRESS

It has often been assumed that a direct cause of Florida Bay's ecological changes is a long-term increase in the Bay's salinity that resulted from the diversion of freshwater away from Florida Bay via SFWMD canals. However, recent research has indicated that the Bay's changes are not attributable to a single cause - while decreased freshwater inflow and resultant increased salinity have been part of the problem, it appears that other human activities, as well as natural forces, have also contributed to the problem (Armentano et al. 1997, Boesch et al. 1993, Boesch et al. 1995, Boesch et al. 1997, Fourqurean and Robblee 1999). The conceptual model thus includes both natural and human derived sources of stress (refer to figure on page D-A-116).

Altered salinity regime. The salinity regime of an estuary is a primary determinant of the species composition of communities, as well as strongly influencing functions of these communities (Sklar and Browder 1998). Salinity is a direct stress on biota; all estuarine biota have adapted to a given salinity range and a given degree of salinity variability. For a given organism, changing salinity beyond this range or too quickly within this range can result in poor health or death. Thus long-term changes in salinity *level or variability* are detrimental to some species, but favorable for other species.

Florida Bay's salinity regime varies greatly over time and space. This variation ranges from coastal areas that can be nearly fresh during the wet season, to large areas of the central bay that can have salinity levels near 70 ppt during prolonged droughts, to nearly stable marine conditions (about 35 ppt) on the western boundary of the bay. The main forces that determine salinity regime in the bay are the inflow of freshwater from the Everglades, rainfall over the bay, evaporation from the bay, and exchange with seawater from the Gulf of Mexico and the Atlantic Ocean. Both freshwater inflow and seawater exchange have changed drastically in the past hundred years, resulting in an alteration of the bay's salinity regime.

Freshwater inflow to Florida Bay decreased in volume and changed in timing and distribution during this century because of water management. Hydrologic alteration began in the late 1800s, but accelerated with the construction of drainage canals by 1920, the Tamiami Trail by 1930, and the C&SF Project and South Dade Conveyance System from the early 1950s through 1980 (Light and Dineen 1994). With the diversion of freshwater to the Atlantic coast and Gulf of Mexico coast, the bay's mean salinity inevitably increased. The extent of this increase and how the variability of salinity changed is not known, but is the subject of current research.

Results from this research indicate that another important development that altered the salinity regime of Florida Bay was construction of the Flagler railway across the Keys from 1905 to 1912 (Swart et al. 1996, Swart et al. 1999). It appears that in the last century, prior to railway construction and water management, Florida Bay had a lower mean salinity and more frequent periods of low (10 ppt - 20 ppt) salinity than during this century. The extent and frequency of high salinity events does not appear to have changed between centuries. The bay's salinity regime changed abruptly around 1910 because passes between the Keys were filled to support the railway. Thus, water exchange between Florida Bay and the Atlantic Ocean was decreased and water circulation throughout the bay was probably altered.

Two important natural controls of salinity, sea level rise and the frequency of major hurricanes must also be considered. Florida Bay is a very young estuary, the product of sea level rising over the shallow slope of the Everglades during the past 4000 years. With rising sea level, the bay not only became larger but also became deeper. With greater depth, exchange of water between the sea and the bay probably increased, resulting in a more stable salinity regime with salinity levels increasingly similar to the sea. However, a factor that has counteracted the rising sea is the accumulation of sediment, which makes the bay more shallow. Most sediment that accumulates in Florida Bay is carbonate that is precipitated from water by organisms that live in the Bay. The extent to which these sediments accumulate is a function of the biology of these organisms, the chemistry of the water, and the physical energy available to transport these sediments from the Bay. Major hurricanes are thought to be important high energy events that can flush the bay of these sediments. However, since 1965, no major hurricane has directly affected Florida Bay. Florida Bay's ecological changes during the past decade may thus be indirectly influenced by changing circulation patterns and resultant changing salinity regimes because of changing water depth in the bay.

Nitrogen and phosphorus inputs. The productivity and food web structure of all ecosystems is strongly influenced by patterns of nutrient cycling and the import and export of these nutrients. Throughout the world, estuarine ecosystems have undergone dramatic ecological changes because they have been enriched by nutrients derived from human activity. These changes have often been catastrophic, with the loss of seagrasses and the occurrence of algal blooms and lethal low oxygen or anoxic events. The input of nitrogen and phosphorus (N and P) to estuaries is thus a potentially important stressor of estuaries.

The importance of N and P as stressors in Florida Bay is unclear. In general, the bay is rich in N and poor in P, especially towards the eastern region of the bay

(Boyer et al. 1997). There is little evidence that nutrient inputs to the bay have increased during this century, but with expanding agriculture and residential development in south Florida through this century, and particularly development of the Keys, nutrient enrichment almost certainly has occurred (Lapointe and Clark 1992, Orem et al. 1998). Anthropogenic nutrients that enter Florida Bay are derived not only from such local sources (fertilizer and wastes from agriculture and residential areas), but also from remote sources. It is likely that remote contributions to the Gulf of Mexico, such as from the phosphate fertilizer industry of the Tampa-Port Charlotte area and residential development from Tampa to Naples, are the most important external sources of nutients (Rudnick et al. 1999). This enrichment from external sources, however, may not less important to the bay's ecology than it's own internal sources and cycling. It is, nevertheless, a reasonable hypothesis that a chronic increase in nutrient inputs has occurred in Florida Bay in this century and this increase has contributed to ecological changes. Ongoing research will provide information to test this hypothesis. Development of a water quality model will also help us understand the effects of past nutrient inputs and predict the effects of future management scenarios.

In the conceptual model, water management is listed as a source of stress because the canal system can transport nutrients through the wetlands toward the bay, decreasing nutrient retention by the wetlands and possibly increasing nutrient inputs to the bay. Nutrient inputs from the Everglades and the Gulf of Mexico are affected not only by changes of freshwater flowing from Taylor Slough and Shark River Slough, but also by changes in bay circulation. Nutrient retention within the Bay is certainly sensitive to these changes in circulation, which have been caused by Flagler railway construction and the balance of sea level rise and sedimentation or sediment removal by major hurricanes. The influence of hurricanes may be particularly important, as nutrients (particularly P) accumulate in the bay's carbonate sediment and the absence of major hurricanes may have resulted in an accumulation of nutrients during the past few decades.

Pesticides and mercury. With the widespread agriculture and residential development of south Florida, the application and release of pesticides and other toxic materials has increased. Mercury is of particular concern because of high concentrations of methylmercury in upper trophic level species. However, it is unclear whether anthropogenic mercury inputs to the Everglades or Florida Bay have increased or whether mercury cycling and methylation rates have changed. Pesticides and mercury are of concern because they can affect human health after the consumption of fish or other biota with high concentrations of these toxins, and because other species may be adversely affected by these compounds. To date, there is no evidence the main ecological changes in Florida Bay are in any way linked to inputs of toxic compounds. Water management affects the distribution of these toxic materials and potentially their transport to Florida Bay. Controlling water levels in wetlands may also influence the decomposition of pesticides and mercury methylation rates because both of these processes are sensitive to the presence of oxygen in soils, which is affected by water levels.

Fishing pressure. For any species that is the target of recreational or commercial fisherman, fishing pressure directly affects population dynamics and community structure. Within Everglades National Park, commercial fishing has been prohibited since 1985, but populations that live outside of ENP boundaries for at least part of their life cycle, which includes most of Florida Bay's sport fish species, are nevertheless affected by fisheries (Tilmant 1989).

D-A.9.4 ESSENTIAL ECOSYSTEM ATTRIBUTES AND LINKS TO STRESSORS

A set of Florida Bay's attributes that are either indicators of the health of the ecosystem or intrinsically important to society are given in the conceptual model. These attributes in most cases are biological components of the ecosystem, including seagrass, molluscs, shrimp, fish and birds, but also an aggregated attribute of the chemical and physical condition of the bay, termed "water quality condition." While the list of biological components is broad, it is clear from the links to stressors that are presented that these attributes are not equally weighted within the model; the central attribute of this conceptual model of Florida Bay is the seagrass community. Details of each attribute and linkage are given below.

Seagrass community. The keystone of the Florida Bay ecosystem is its seagrasses (Zieman et al. 1989, Fourqurean and Robblee 1999). These plants are not only a highly productive foundation of the food web, but are also the main habitat of higher trophic levels and a controller of the bay's water quality. Understanding how seagrasses affect water quality is essential for understanding the current status and fate of the bay.

Seagrasses affect water quality by three mechanisms: nutrient uptake and storage, binding of sediments by their roots, and trapping of particles within their leaf canopy. With the growth of lush seagrass beds, these mechanisms drive the bay towards a condition of clear water, with low nutrients for algae growth in the water and low concentrations of suspended sediment in the water. During the 1970s through the mid-1980s, lush *Thalassia* beds grew throughout central and western Florida Bay and the water was reported to be crystal clear. We hypothesize that with the onset of a *Thalassia* mass-mortality event in 1987 (Robblee et al. 1991), these mechanisms reversed, initiating a cycle that causes continued <u>seagrass habitat loss</u> and propagates persistent turbid water with algae blooms (Stumpf et al. 1999).

The cause of the 1987 mass-mortality event is not known, but thought to be related to earlier changes in two stressors, the salinity regime and nutrient availability. These changes caused *Thalassia* beds to grow to an unsustainable density by the mid 1980s. It is also likely that a decrease in shoal grass and widgeon grass (*Halodule* and *Ruppia*) occurred with the *Thalassia* increase. *Thalassia* "overgrowth" may have occurred because the species thrived when the salinity regime of the bay was stabilized, with few periods of low salinity. Nutrient enrichment also may have played a role, with a chronic accumulation of nutrients caused by increased inputs over decades or decreased outputs because of the absence of major hurricanes or closure of Keys' passes. The factors that conspired to initiate the mass-mortality event in 1987 are also unknown, but thought to be related to the high respiratory demands of the dense grass beds and accumulated organic matter. During the summer of 1987, with high temperatures, sulfide levels may risen to lethal concentrations.

Regardless of the cause of the mass-mortality event, once this event was initiated, the ecology of Florida Bay changed. The cycle causing continued seagrass habitat loss, which characterizes the present Florida Bay, is illustrated in the model. Continued seagrass mortality results in increased sediment suspension and increased nutrient release from the sediments (>N & P), stimulating the growth of algae in the water column. The presence of both these algae and suspended sediment result in decreased light penetration to the seagrass bed. In this cycle, it is this decreased light that stresses the seagrasses and sustains the feedback loop. Light penetration is thus an essential aspect of the attribute, water quality.

The dynamics of this feedback loop are probably not independent of the salinity regime. A disease of seagrass, caused by a slime mold infection, seems to be more common at salinities near or greater than seawater (35 ppt) than at low (15 to 20 ppt) salinities (Landsberg et al. 1996). This may have played a role in either the initial seagrass mass mortality event, but more likely has served to continue seagrass mortality since that event. The incidence of this disease may be directly affected by water management actions.

If the state of the seagrass community is to be used as a criterion to decide the success of environmental restoration efforts, environmental managers must specify the desirability of alternative states. The consensus among scientists is that the Florida Bay of the 1970s and early 1980s, with lush *Thalassia* and clear water, was probably a temporary and atypical condition. From an ecological perspective, restoration should probably strive for a more diverse seagrass community, less dominated by *Thalassia* than during that period.

Water quality condition. Water quality condition reflects not only obvious characteristics, such as salinity, but also the light field, algae in the water column, and the availability of nutrients in the ecosystem. All of these characteristics are closely related to the condition of seagrasses and the food web structure and dynamics of the bay. While these characteristics have been monitored and researched since the early 1990s, earlier information is scarce for salinity and even less available for other characteristics. Thus, at the present time, we do not know whether nutrient inputs to the bay have actually increased in recent decades or whether periods with sustained algal blooms and high turbidity occurred in the past.

Salinity has frequently been suggested as a primary restoration target. However, establishing salinity success criteria, such as those used in the Restudy's evaluation of the effects of hydrological alternatives on coastal salinity, depends on the development of a model of the "natural" salinity distribution of Florida Bay in time and space. This requires a both a water budget for the bay (monitoring rainfall, evaporation, and freshwater flow, water level, and salinity) and a hydrodynamic model, which is now under development. With modeled salinity variability for a wide variety of target sites in the bay, the fit of observed salinity fields to modeled fields could serve as the basis of deciding levels of success.

The magnitude of nutrient inputs to the bay, and their relationship to freshwater inputs is under investigation. Success criteria based on water column nutrient concentrations are probably less meaningful than criteria based on nutrient loading. Preliminary results indicate that phosphorus loads to the bay do not greatly increase with increased freshwater inputs (Rudnick et al. 1999), but Florida Bay is probably very sensitive to any increase in P availability. Unlike phosphorus, nitrogen loads probably do increase with more freshwater flow and algae blooms in western and central Florida Bay appear to be stimulated by increased N (Tomas 1996).

Finally, as emphasized earlier, the penetration of light through Florida Bay waters is a key to the health of seagrasses. An important success criterion should be light penetration, which is largely a function of turbidity from algae and suspended sediment. Light penetration should be sufficient to support a viable seagrass habitat. Such light-based criteria have been used successfully in other estuaries.

Molluscs. Because of our ability to assess historical community structure, molluscs are a good indicators for the entire ecosystem. The composition and activity of the molluscan community is a function of salinity, seagrass and other habitat availability, and food supply. Studies of long-term changes in the composition of this community (by analyzing shells in the sediment) have indeed found changes that reflect the large-scale changes of the bay's salinity regime. Furthermore, molluscs are likely to be important as grazers of algae in bay waters; the trophic status of the bay is reflected by molluscan community composition.

Pink shrimp. Pink shrimp are intrinsically important to society as an economic asset. They are also ecologically important, serving as a major component of the diet of game fish and wading birds; pink shrimp are an indicator of the bay's productivity. Florida Bay and nearby coastal areas are a primary nursery ground for pink shrimp - a nursery that supports the shrimp fishery of the Tortugas Grounds (Costello and Allen 1966). Hydrological and ecological changes in the Everglades and Florida Bay may have impacted this fishery, which experienced a decline in annual harvest from about 10 million pounds per year in the 1960s and 1970s to as little as 2 million pounds per year in the late 1980s (Ehrhardt and Legault 1999). This decline may have been associated with seagrass habitat loss or high salinity (50 to 70 ppt) during the 1989-1990 drought; experiments have shown that pink shrimp mortality rates increase with salinities above 40 ppt (Browder et al. 1999). Shrimp harvest statistics indicate that shrimp productivity increases with increasing freshwater flow from the Everglades (Browder 1985).

Fish populations. The health of Florida Bay's fish populations is of great importance to the public; the sport fishing is a major economic asset to the region. It is clear from recent studies that seagrass beds and the mangrove zone are important habitats for fish, but no dramatic bay-wide decreases in total fish abundance have been observed along with seagrass mass-mortality (Thayer et al. 1999). Rather, a shift in the species composition of this upper trophic level has occurred as a result of the cycle of seagrass habitat loss and sustained algae blooms. While some fish species have declined, fish that eat algae in the water, such as the bay anchovy, are thriving. Thus the stressors, such as altered salinity, not only affect upper trophic level animals directly, but also affect them indirectly through food web changes.

Another important stressor that needs to be considered with regard to fish populations is the impact of pesticides and mercury. As concentrations of mercury and some pesticides greatly increase in upper trophic level animals, such as sport fish, (via the process of bioaccumulation), and people eat such fish, a human health issue potentially exists. Pesticides and mercury can also have ecological impacts by physiologically stressing organisms (particularly reproductive functions). The extent of any existing problem with these toxic compounds in Florida Bay is being investigated, but they currently do not appear to significantly impact human health or ecological health in the bay. The possible impact of future restoration efforts on these issues, however, must still be considered.

Among the many fish species that could be used as indicators of the health of the ecosystem's upper trophic level, there is consensus among scientists that spotted sea trout is a key species. This is the only major sport fish species that spends its entire life-span in the bay. Population changes and toxic residues in this species thus reflect the specific problems of the bay and should also reflect the restoration actions that we take. For northeastern Florida Bay, the abundance of snook, tarpon, and crevalle jack should also be considered.

Birds. Florida Bay and its mangrove coastline is an important feeding ground and breeding ground for water fowl and wading birds. Conceptual models for other regions of the Everglades, particularly the mangrove - estuarine transition zone conceptual model, present more detailed descriptions of the use of bird populations as ecological indicators and consider a wide variety of birds. For the Florida Bay conceptual model, we consider only fish-eating birds, such as osprey, brown pelicans, and cormorants. These birds are important predators of fish in the bay and are potentially impacted by any stressors that affect their prey base, including salinity changes, nutrient inputs, toxic compounds, and fishing pressure. As with other top predators, these bird species are the most vulnerable members of the ecosystem with regard to pesticide and mercury effects.

D-A.9.5 MEASURES

A list of fundamental measures associated with each of the model's ecosystem attributes is given. This list should be considered minimal; interpretation of many of these measures requires a set of associated measures. The list includes not only "structural" variables (for example, pink shrimp abundance), but also dynamic, process variables (for example nutrient fluxes). Note that this list does not reflect the temporal or spatial time scale at which measurements are necessary, but temporal patterns, such as seasonality and interannual variability, and spatial patterns are a central aspect of ecological dynamics. Also note that the power to predict the fate of any ecosystem requires more than monitoring; research and modeling are also essential components of sound environmental management.

Performance Measure
Seasonal Distribution of Overland Flow Volume, Mid Shark River Slough

Date Submitted/Revised
June 1988

General Planning Objective

This performance measure is linked to the Everglades Sloughs Conceptual Model developed by the SERA Natural Systems Team, and addresses several hydrologic and ecologic planning objectives identified by the Governors's Commission for a Sustainable South Florida in the C&SF Project Restudy Conceptual Plan.

Region

The seasonal distribution of overland flow volume is applied as a performance measure only to the cross section in mid Shark River Slough.

Restoration Goal

The re-distribution of flow into Shark River Slough, with subsequent restoration of extended duration of uninterrupted flooding, brief duration of dry conditions, water depth pattern, and overland flow volume and **timing characteristic** of the pre-drainage system is among the highest priorities of ecosystem restoration in the southern Everglades.

Problem Addressed

Restoration of the seasonal timing of flow down Shark River Slough is important to extend the duration of flooding in the Slough and to provide seasonal salinity patterns in the estuaries as they would have occurred in the natural system

Model Target

The target is a cumulative deviation that does not exceed that indicated by NSM45F.

Model Output Format

The overland flow volume across the cross-section in mid Shark River Slough that occurs each month of the year is calculated as the percent of the annual flow volume and is averaged over the 31-year period of record. The performance measure is the cumulative deviation of the monthly percent of annual flow under a given alternative from the monthly percent of flow under NSM45F, summed over the 12 months of the year. It is given a weighting of one when averaged with the other performance measures for Shark River Slough because of the higher level of uncertainty in NSM45F simulations of flow compared to other parameters.

Evaluation Tools

The South Florida Water Management Model and Natural System Model should be used to evaluate a cross section evaluate a cross-section taken across the entire width and depth of flow in mid Shark River Slough.

Performance Measure

Florida Bay Performance Measure Suite:
Frequency of Stages of 6.3+ feet MSL at Gage P33
Frequency of Stages of 7.3+ feet NSM at Gage P33
Cumulative Salinity Differences from High Levels, March-June
Cumulative Salinity Differences from Low Leves, August-October

Date Submitted/Revised

June 1998

General Planning Objective

These performance measures are linked to the Florida Bay Mangrove/Estuarine Conceptual Model developed by the SERA Natural Systems Team.

Region

All four measures target Florida Bay coastal basins.

Restoration Goal

Ecological values and indicators of restoration success in the Florida Bay mangrove estuary and coastal basins that are linked to the above hydrology/salinity performance measures in the conceptual model include 1) increased production of low-salinity mangrove fish and invertebrates, 2) re-establishment of coastal nesting colonies of wading birds and wood storks and eastern Florida Bay colonies of roseate spoonbill, 3) delay (syn) in coastal colony formation by wading birds and wood storks, 4) resumption of the return frequency of wading bird and white ibis super colonies, 5) increased growth and survival of juvenile American crocodiles, 6) increased cover of low-to-moderate salinity aquatic macrophyte communities in coastal lakes and basins, 7) return of seasonal waterfowl aggregations to coastal lakes and basins, 8) enhanced nursery ground value for sport fishes and pink shrimp in coastal basins, and 9) persistence and resilience of the mangrove, salt marsh and tidal creek vegetation mosaic.

Problem Addressed

Ecological restoration of the estuary requires a reduction in the frequency of high salinity events that have been identified for each coastal basin through the conceptual model process. Another restoration criterion is to increase the frequency of low salinity events that have been identified for each coastal basin.

Table 1. Lower and upper salinity levels identified for coastal basins. It is desirable to decrease the frequency that salinity exceeds upper levels, and to increase the frequency that salinity drops below lower levels.

Basin	Lower Level	Upper Level
Joe bay	5 ppt	15 ppt
Little Madeira Bay	15 ppt	25 ppt
Terrapin Bay	25 ppt	35 ppt
Garfield Bight	25 ppt	35 ppt
North River Mouth	5 ppt	15 ppt

The strategy for ecological restoration of the estuary is to maintain freshwater heads and flows in the Everglades at the upstream end of the salinity gradient in order to achieve desirable salinity regimes in the Florida Bay coastal basins at the downstream end of the salinity gradient. Regression analyses demonstrated inverse relationships of salinity in the coastal basins to water level upstream in the Everglades. The regressions indicated that stages of 7.3 and 6.3 feet msl at the P33 gage in central Shark River Slough produce the lower and upper salinity levels for Joe Bay, Little Madeira Bay, Terrapin Bay, Garfield Bight, and North River Mouth.

Model Target

Number of months NSM4.5F provided stages of 6.3 or above
Number of months NSM4.5F provided stages of 7.3 or above
Reduce the cumulative salinity difference to a value that does not exceed the cumulative difference produced by NSM4.5F.
Reduce the cumulative salinity difference to a value that does not exceed the cumulative difference produced by NSM4.5F.

Model Output Format

The Florida Bay Mangrove/Estuarine Conceptual Model identifies high salinity concentrations for the coastal basins of Florida Bay which should not be exceeded more frequently than NSM45F would indicate. Stages equaling or exceeding 6.3 feet msl at the P33 gage in mid Shark River Slough correspond to a reduced frequency of those high salinity events in the the Florida Bay coastal basins from Joe Bay to North River Mouth. This performance measure is the number of months during the 31-year period of record when stages at P33 rose to, or above, 6.3. A reduced frequency of high salinity events is given a high priority in the ecological restoration of the coastal basins, thus the frequency of 6.3+ stages is given a weighting of two when averaged with the other performance measures.

The Florida Bay Mangrove Estuarine Transition Conceptual Model identifies low salinity concentrations for the coastal basins of Florida Bay which should be attained as frequently as NSM45F would indicate. Stages equaling or exceeding 7.3 feet msl at the P33 gage in mid Shark River slough corresponded to an increased frequency of those low salinity events in the coastal basins of Florida Bay. The performance measure is the number of months during the 31-year period of record when stages at P33 rose to, or above, 7.3. An increased frequency of low salinity events is given a lower priority than a reduced frequency of high events, thus the frequency of 7.3+ stages is given a weighting of one when averaged with the other performance measures for the coastal basins.

The transition from the late dry season to the early wet season during March through June is a critical period to estuarine organisms in the Florida Bay coastal basins regarding the frequency and duration of high salinity events. Salinity is estimated based on relationships between mean monthly salinity in the coastal basins and water stage at the P33 gage in mid Shark River Slough. The cumulative salinity difference (ppt) from the high salinity levels that have been identified for Florida Bay coastal basins is summed during the dry/wet season transition months of March-June. Differences are summed over five coastal basins (Joe Bay, Little Madeira Bay, Terrapin Bay, Garfield Bight and North River Mouth) and over the 31-year period of record. Differences above the specified high salinity levels are given a positive value, and differences below the high salinity levels are given a negative value. This measure is given a weighting of two when averaged with the other performance measures for the coastal basins because the avoidance of high salinity events is considered more important than the attainment of low salinity events.

During the August-October transition from the late wet season to the early dry season, it is important to achieve low salinity levels in the Florida Bay coastal basins to provide the seasonal environment for low-salinity estuarine organisms and to postpone the onset of high salinity events further into the dry season.

Salinity is estimated based on relationships between mean monthly salinity in the coastal basins and water stage at the P33 gage in mid Shark River Slough. The cumulative salinity difference (ppt) from the low salinity levels that have been identified for the Florida Bay coastal basins is summed during the wet/dry season transition months of August-October. Differences are summed over the five coastal basins and over the 31-year period of record. Differences above the specified low salinity levels are given a positive value, and differences below the low salinity levels are given a negative value. This measure is given a weighting of one when averaged with the other performance measures for the coastal basins because the attainment of low salinity events is considered less important than the avoidance of high salinity events.

Evaluation Tools

The South Florida Water Management Model and Natural System Model should be used to evaluate P33 stages. Priority is given to the P33 stage of 6.3 and the March-June cumulative salinity difference, which pertain to the avoidance of high salinity levels, over the P33 stage of 7.3 and the August-October cumulative salinity difference, which pertain to the achievement of low salinity levels

Model Lands/C-111 Performance Measure Suite
High Water
Low Water
Extreme Low Water
Relative Dry Period Slope
Wet Season Inundation Pattern
Late Wet Season Inundation

Date Submitted/Revised

March 1998/July 1998

General Planning Objective

Meets planning objective criteria identified by the SERA Natural System Team and by the Governor's Commission for a Sustainable South Florida.

Region

The term Model Lands, for C&SF Restudy planning purposes, applies to three areas: (1) wetlands immediately north of the C111 Canal, (2) the land between U.S. 1 and Card Sound Road, and (3) land east of Card Sound Road and south of the Mowry Canal (C-103). These areas correspond to Indicator Regions 4 (C-111 Perrine Marl Marsh), 5 (Model Lands South), 6 (Model Lands North), and 47 (North C-111).

Restoration Goal

Reduce artificial hydrological barriers between indicator regions, minimize the amount of time exceedingly high and low water levels stress natural vegetation communities, and restore more natural hydropatterns.

Problem Addressed

The Model Lands/C-111 region encompasses freshwater (predoninantly marl prairie) wetlands, a transition zone, and coastal wetlands. This area has been subdivided and hydrologically isolated from the regional system by primary and secondary canals and major and minor roads. The result has been widespread overdrainage and a reduction in the amount of freshwater reaching the coastal mangroves and nearshore estuarine waters as overland flow.

A study by Meeder et al. (1996) compared recent vegetation to vegetation mapped during the 1940's by Egler (1952). Their work indicated that a zone of low plant cover and low primary productivity, which is observable as a "white zone" on aerial photographs, has expanded inland by as much as 300 meters since 1940. Meeder et al. (1996) associated the inland expansion of this zone with saltwater intrusion.

Surface water connection between the vast freshwater wetlands in this region has been disrupted and runoff to the coastal bays and sounds have been blocked or diverted by U.S. 1, Card Sound Road and borrow ditches, canal levees, and other man-made structures. Ishman's (1998) paleoecologic study of Manatee Bay suggests that the bay supported a lower salinity fauna in the early part of this century than it does today. Although large quantities of fresh water are sometimes flushed to Manatee Bay through the C-111 Canal (S-197), the point source delivery and pulsed manner in which this water moves into Manatee Bay has proved harmful to marine and estuarine life. Most of the time Manatee Bay receives little freshwater inflow.

Model Target

The Natural System Model (NSM) was not used to set performance targets for this region. NSM is not a good indicator of pre-drainage hydrologic conditions in the Model Lands area, as evidenced by NSM predictions of lower dry-season water levels than the 1995 Base. If current water levels were higher than pre-drainage water levels, it is unlikely that the "white zone" would have expanded to the degree that it has since 1940. Additionally, there had to have been sufficient freshwater flows to Manatee Bay at most times of the year to support a brackish water fauna, which does not exist in modern times. Four indicator regions in the Model Lands area were established for the study of alternative management scenarios. Specific target water levels and hydroperiods were defined for these indicator regions based on known topography and projections of future restored vegetation. Vegetation zones adapted from Meeder et al. (1996) were the basis for establishing target water levels. The collective professional experience of a team of biologists from federal, state, and local agencies and businesses was the basis for setting desired maximum ponding depths, minimum water levels, and hydroperiods for each vegetation zone. Indicator regions and the projected desired hydrologic parameters are shown below, followed by the vegetation zones applicable to each indicator region. Maximum and minimum water levels are relative to ground level.

Indicator Region	Region Name	SFWMM Cells	Max Ponding Depth - Wet Season	Min Water Level - Dry Season	Average Hydroperiod	Vegetation Zones Included
4	C-111 Perrine Marl Marsh	R8, C26-27 R7, C26-27	< 2.0 ft	> 0.5 ft	10 - 12 months	3
5	Model Lands South	R8, C29-30	< 2.0 ft	> 0.5 ft	10 - 12 months	3
6	Model Lands North	R10, C29-30	< 1.75 ft	> 0.25 ft	8 - 12 months	2 + 3
47	North C-111	R9, C26-27	< 1.5 ft	> 0 ft	6 - 9 months	2

Vegetation zones used as the basis for establishing targets

Zone	Descriptive Name	Desired Wet Season Maximum Water (relative to ground elevation)	Desired Dry Season Minimum Water (relative to ground elevation)	Desired Average Hydroperiod
0	Agriculture/Open Land Buffer	N/A	N/A	N/A
1	Shrub-dominated Freshwater Marshes	< 0.5 ft	> -0.5 ft	Driven by downstream hydrology
2	Muhly/Sawgrass or Sawgrass Mosaic with Tree Islands	< 1.5 ft	> 0 ft	6 - 9 months, no wet season reversals
3	Sawgrass Marsh with Freshwater Swamp Forests	< 2.0 ft	> 0.5 ft	10 - 12 months, no wet season reversals
4	Mixed Graminoid with Dwarf Mangroves	Driven by upstream maxima	> 0.5 ft	12 months
5	Ecotone - "White Zone"	*	*	12 months
6	Fringing (aka Coastal) Mangroves	**	**	12 months
7	Downstream Marine Areas	N/A	N/A	N/A

Water level not a useful indicator; 0 - 3 ppt salinity desired. year round.

** Water level not a useful indicator; 0 - 5 ppt salinity desired. year round.

Model Output Format

High Water: The proportion of time that water levels are below the high water level which has been specified for the indicator region.

Low Water: The proportion of time that water levels are below the low water level which has been specified for the indicator region.

Extreme Low Water: The proportion of time that water levels stay above one foot below the low water target.

Relative Dry Period Slope: Relative measure of the steepness of the slope for the stage duration curve during dry periods.

Wet Season Inundation Pattern: Proportional measure of how many times during the 31 year simulation that water levels drop below surface elevation during the July-October portion of the wet season.

Late Wet Season Inundation: Proportional measure of how many times during the 31-yr simulation that autumn periods of inundation ended during the months of November and December.

This was applied only to Indicator Region 5 (Model Lands South), which includes habitat critical for Roseate Spoonbill feeding.

Performance Measure

Wood Stork Nesting Patterns

Date Submitted/Revised

May 1998

General Planning Objective

Meets SERA objectives to (1) Restore the natural annual and multi-year patterns of native plant and animal distribution, abundance, seasonality and richness to the natural areas of the southern Everglades region, and (2) Provide for self-sustaining and self-regulating populations of native plant and animal species with special attention to threatened, endangered and species of special concern (includes both state and federally listed species).

Meets general planning objectives of the Conceptual Plan for the C&SF Restudy Project, of the Governor's Commission for a Sustainable South Florida, to (1) Improve and protect habitat quality, heterogeneity, and biodiversity in coastal and associated marine ecosystems, and (2) Provide for sustainable populations of native plant and animal species with special attention to threatened, endangered, or species of special concern.

Region

Southern Everglades & Big Cypress Subregions

Restoration Goal

Recover healthy, sustainable Wood Stork nesting colonies to the Everglades basin.

Problem Addressed

The number of Wood Storks nesting in colonies in the central and southern Everglades has declined from 5,000-8,000 birds prior to the C&SF Project (numbers are for 1931-1946) to 250-1,000 birds since 1986 (Ogden 1991, 1994, Gawlik & Ogden 1996). During this same spread of years (1931-1996) the timing of colony formation (initiation of nesting) by storks has shifted from November & December for most years prior to 1970, to February & March for most recent years (Ogden 1994). Earlier forming colonies were larger and more successful than late forming colonies (e.g., means of 2,250 pairs in November colonies, and 450 pairs in March colonies; successful in 7 of 9 years between 1953-1961, but successful only 6 of 28 years between 1962-1989. Early forming colonies were located almost entirely within the mainland, mangrove forest zone downstream from the freshwater Everglades drainage, or along the mangrove-freshwater ecotone in the southern Everglades. Recent stork colonies mostly have been located on willow and pond apple islands in the south-central Everglades.

The hypothesis which best explains the changes in nesting patterns by storks is that, as a result of substantial reductions in freshwater flow into the mainland estuaries, the production and availability of the size classes of fishes which are essential prey for nesting storks has deteriorated to the point where the mangrove zone can no longer support nesting by storks (Ogden 1994). Storks now "wait" until water levels in the later-drying interior sloughs drop low enough for fish to be adequately concentrated to support nesting activity. Interior, late-forming colonies often fail because, (a) fish stocks also are relatively low because of increased frequencies of slough dry-outs in the managed system, (b) interior colonies lack the range of foraging habitat conditions found in estuarine systems, and (c) late colonies are still active when summer rains disperse local prey concentrations.

Model Target

To recover healthy, sustainable nesting colonies of Wood Storks in the Everglades basin, storks must return to nesting in the area of the mainland estuaries, with colonies forming no later than January. The historical pattern was for storks to forage primarily in the mainland estuarine region during the early dry season at the time of colony formation, and to forage in the drying freshwater sloughs during the later dry season during the nestling and fledging stages of reproduction.

In addition to recovery of traditional location and timing patterns, the Science Sub-Group of the South Florida Ecosystem Restoration Task Force and Working Group set a ecosystem restoration target of 3,000 - 5,000 nesting storks for the Everglades and Big Cypress colonies combined (Ogden et al. 1997). This numerical target is consistent with the target set in the revised Wood Stork Recovery Plan for delisting the stork: 2,500 pairs (5,000 birds) nesting in south Florida in a total population of 10,000 pairs (U.S. Fish and Wildlife Service, 1996).

Model Output Format

The two hydrological indicators which best measure the recovery of optimum foraging conditions for storks for the restoration targets described above, are, (a) the measures of the volume of flow into the mainland estuaries downstream from the southern Everglades and Big Cypress (three flow lines; one across the southern

Shark Slough; one across the southern Taylor Slough/Craighead Basin; and one across the Lostman's Slough), and (b) the measure of mean duration of uninterrupted surface hydroperiod in the central and southern Shark Slough (indicator regions 10 and 11). The target is to meet NSM 4.5 predicted flow volumes and hydroperiod durations, respectively. The "score" for each alternative plan and base condition will be the simple mean of the percentages of NSM targets for the five hydrological parameters (3 flow lines and 2 indicator regions). This calculation results in greater weight for the estuarine target, because three of the five values are for measures of flow into the estuaries. Greater weight for the estuarine target is appropriate because achievement of the desired colony timing and location patterns may be dependent of estuarine conditions.

Evaluation Tools

Uses output from the South Florida Water Management Model and the Natural Systems Model (4.5), for Indicator Regions 10 and 11 in the central and southern Shark Slough, and 3 Flow Lines at the freshwater/estuarine ecotone (Taylor Slough, Shark Slough, Lostmans Slough).

Performance Measure
Viable Populations of the Endangered Cape Sable Sparrow

Date Submitted/Revised
November, 1998

General Planning Objective

Meets Governor's Commission planning objective in the C&SF Project Restudy Conceptual Plan; to provide for sustainable populations of native plant and animal species with special attention to threatened, endangered, or species of special concern.

Region

Everglades National Park and Big Cypress National Preserve

Restoration Goal

For the sparrow to survive in the long-term, there must be three healthy sub-populations, each averaging at least 2000 birds.

Problem Addressed

The Cape Sable sparrow is a Federally listed endangered species found only within the southern Everglades. First found early in this century, its exact range was not known completely until an extensive survey was completed in 1981. Approximately 6500 existed at that time, grouped into three areas. The one west of Shark River Slough (A) was the most numerous, followed by a slightly smaller population east of the Slough and west of Taylor Slough (B). The remaining birds were scattered in populations to the north and east of these two areas (C through E). In 1992, the second annual survey found similar numbers, though the northeastern birds had declined. In 1993, the western population declined precipitously and has remained at low levels since. Population B has remained more or less constant. The remaining populations have been marked by declines and local extinction (Curnutt et al.,l998)

Analysis of the causes of these declines rule out chance fluctuations in numbers (which can be large for similar grassland sparrows) and Hurricane Andrew, which passed over some of the populations in 1992 (Curnutt et al., l998) Persistent high water levels during the bird's breeding season (mid-March to mid-June) are the cause of the decline in the western part of the range. High water levels - caused principally by discharges across the S12 structures during the early months of the year - prevented breeding in 1993 and 1995 and allowed only limited breeding in 1994, 1996, and 1997 (Nott et al., l998). Rainfall during the breeding season has a much smaller effect on the water levels in this area. In the north and east of the sparrow's range, frequent fires caused the decline in sparrow densities. Fires as often as once a year preclude breeding, and sparrow numbers increase as fire frequencies decline to once in seven years. This frequency is the limit of the data. It seems possible that the diversion of water flows from northeast Shark Slough is partly responsible for the drier conditions there, which could result in more frequent fires and, in turn, the decline of the sparrow population.

Model Target

An area of 30 square kilometers in the west should remain dry (water level at or below ground level) for a least 40 days during the period mid-March to mid June. This will allow the birds to complete one clutch. This is a minimum safe standard for wet years, not an average value. Under average conditions, an area of approximately 100 square kilometers would be dry and part of this area would be dry for at least 80 days - the time taken to complete two clutches.

In the northeast part of the sparrow's range, the water levels need to be raised during the pre-breeding season in a way necessary to reduce fire frequencies across the area to a safe minimum standard of no more than one dry season fire in three years.

The first requirement is that the water level at NP205 should be at or below ground level on April 1st of each year. This will ensure that sufficient breeding habitat is available for the population west of Shark River Slough.

The second requirement is that water levels in the marl prairies to the east of Shark River Slough and north of Long Pine Key should be raised at the end of the rainy season by about 12 cm (= 5 inches) above recent averages.

Performance Measure

Inundation Pattern (number and mean duration of inundation periods)

Date Submitted/Revised
September 1997/June 1998

General Planning Objective

Recovery of historical hydroperiods was identified by the SERA Natural Systems Team as the highest priority for the ecological restoration of the slough/peat system, and was identified as one of the general planning objectives established by the Governor's Commission for a Sustainable South Florida in the Conceptual Plan for the C&SF Restudy Project.

Region
Northern and Central Everglades:
Loxahatchee National Wildlife Refuge (WCA-1)
Holey Land and Rotenberger WMAs
WCA-2A and 2B, WCA-3A and 3B
Pennsuco Wetland

Restoration Goal

A functionally restored system should mimic natural system inundation frequencies and duration.

Problem Addressed

Inundation patterns in the managed Everglades system have been substantially altered from pre-drainage patterns due to water management practices. The ecological impacts of this are detailed in one of the four critical ecological pathways suggested by the Everglades slough conceptual model. This pathway links reduction in water storage capacity and shortened hydroperiods (hydrologic stressors) with ecological responses that include reduced production and survival of aquatic animals, degraded plant community structure and composition, and the spread of exotic vegetation.

Model Target

Target values for duration of inundation and number of events were those predicted by NSM 4.5 Final with two exceptions: (1) Indicator Region 17's performance was evaluated by comparing values to the average of NSM values for Indicator Regions 14 and 18; this was because the NSM depths in this Indicator Region had been identified during evaluation of Alternatives 1-3 as being lower than desirable for this relatively pristine marsh area; (2) in LNWR, the targets were 1995 Base values, in keeping with the refuge's current regulation schedule.

Model Output Format

The average depth during a given week in a given year is calculated for each 2x2 grid cell, and these values are averaged over the set of grid cells within an indicator region to obtain an average depth for the indicator region for that week. The duration of inundation for a year is then calculated as the maximum number of sequential weeks in that year during which water depths averaged above zero for the indicator region. Note that this PM differs from the "hydroperiod" measure used in previous planning efforts, in that here only continuous sequences of inundation are scored, whereas the previous measure calculated percent of the year during which water levels were greater than zero, regardless of whether or not the inundation period was interrupted by a dry out. Results are presented in tabular form and also as the two-part graphic "Inundation Pattern 1965-1980, and 1981-1995".

Evaluation Tools

Output from the South Florida Water Management Model and the Natural System Model 4.5 should be used for the following indicator regions: (groupings correspond to areas with distinct hydrologic performance.)

Loxahatchee NWR (Indicator Regions 26 & 27)
Holey Land & Rotenberger WMAs (Indicator Regions 28 & 29)
WCA-2A (Indicator Regions 24 & 25)
WCA-2B (Indicator Region 23)
NW WCA-3A (N of Alligator Alley & W of Miami Canal; Indicator Regions 20 & 22)

Northeastern WCA-3A (N of Alligator Alley & E of Miami Canal; Indicator Region 21)
Eastern WCA-3A (S of Alligator Alley, E of Miami Canal; Indicator Region 19)
Central & Southern WCA-3A (S of A. Alley, W of Miami Canal; Indicator Regions 14, 17 & 18)
WCA-3B(Indicator Regions 15 & 16)
Pennsuco Wetlands (Indicator Regions 52 & 53)

Water Supply/Resource Protection

Performance Measure

Preventing Salt-Water Intrusion of the Biscayne Aquifer: Percent Time Canal Stage <Salt-Water Intrusions Criteria> 1 Week for Primary Coastal Canal at Selected Structure

Date Submitted/Revised

September 1997

General Planning Objective

Minimum Flows and Levels – SFWMD; Control salt-water intrusion into freshwater aquifers – GCSSFL; Ensure adequate water supply and flood protection for urban, natural and agricultural needs – GCSSFL

Region

Lower East Coast Service Area – Eastern portions of Palm Beach, Broward and Miami-Dade Counties

Restoration Goal

Prevent further encroachment of salt-water interface into the Biscayne aquifer

Problem Addressed

The principal threat to the maintaining the long-term functions of the Biscayne aquifer is salt-water intrusion, i.e. contamination of the aquifer by saltwater. The Biscayne aquifer is located along the eastern edge of Palm Beach County, underlies the majority of Broward County and almost all of Miami-Dade County. Along the aquifer's eastern edge, its fresh water is in contact with the salt water originating from the ocean. The constant westerly flow of fresh water from the Everglades helps to keep the salt water stationary. However, when groundwater levels adjacent to the fresh water/salt water interface are lowered, salt water can potentially move inland replacing the fresh water (Swift *et al*. 1998). The higher density salt water tends to remain inland for long periods of time causing a permanent loss of that portion of the aquifer. Along the Lower East Coast, lowering of the groundwater table due to overdrainage and increased well field withdrawals has allowed salt water to invade and contaminate the Biscayne aquifer during periods of drought (Parker *et al*. 1955). Salt water intrusion of the Biscayne aquifer is considered one of the greatest threats to the long-term water supply of South Florida.

In order to minimize the inland migration of the saline interface, a sufficient head of fresh water must be maintained within the aquifer. Loss of the fresh water head that previously existed west of the Atlantic Coastal Ridge is considered the primary cause of the inland migration of salt water in South Florida (Parker et al. 1955; Fish and Stewart, 1991). The groundwater hydrology of South Florida's Lower East Coast has been permanently altered by urban and agricultural development and construction of the Central and Southern Florida Project. Construction of a series of canals has drained both the upper layer of the Biscayne aquifer and the fresh water mound west of the Atlantic Coastal Ridge. This drainage has reduced the volume of groundwater flowing east and has resulted in the inland migration of saline interface along the entire edge of the aquifer during dry periods. Localized saltwater intrusion has resulted from large coastal wellfields, five of which were partially lost in1939 while others are still threatened today. Construction of coastal canal water control structures, beginning in the 1940s, has helped to stabilize or slow the advance of the saline interface.

Water levels in the coastal canals largely govern the expected inland migration of the saline interface. Managing coastal canals at appropriate water levels during drought periods is a viable option for stabilizing the salt water interface and preventing further inland migration (Swift et al. 1998). The control elevations have been set for the primary canals that receive water from the regional system and have sufficient canal conveyance capacity to receive water from outside their drainage basins.

Model Target

Maintain elevations of primary coastal canals at control structure

Canal - Structure	Canal Stages (ft NGVD)
North New River @ G-54	3.50
Hillsboro Canal @ G-56	6.75
C-51 @ S-155	7.75
C-18 @ S-46	5.00
C-2 @ S-22	2.00
C-4 @ S-25B	2.00
C-6 @ S-26	2.00
C-14 @ S-37B	6.50
C-15 @ S-40	7.75
C-16 @ S-41	7.75
C-9 @ S-29	2.00
C-13 @ S-36	4.00

Model Output Format

Table indicating the target and the number of times and percentage of time the target was not met.

Evaluation Tools

Use output from the south Florida Water Management Model

Performance Measure
Extreme Events:
High Water Extremes
Low Water Extremes

Date Submitted/Revised
September 1997/June 1998

General Planning Objective

The extreme events performance measures address the priority criteria submitted by the SERA Natural Systems Team; the elimination of regulatory operational schedules which cause unnatural depth and duration of flooding patterns. These measures also address several planning objectives identified by the Governor's Commission for a Sustainable South Florida in the C&SF Project Restudy Conceptual Plan; to restore more natural organic and marl soil formation processes and arrest soil subsidence, to provide for sustainable populations of native plant and animal species, to restore and, where appropriate improve, functional quality of natural systems, and to restore more natural hydropatterns.

Region
Northern and Central Everglades:
Loxahatchee National Wildlife Refuge (WCA-1)
Holey Land and Rotenberger WMAs, WCA-2A and 2B, WCA-3A and 3B
Pennsuco Wetland

Restoration Goal

Prevention of peat loss resulting from extreme low water events and protection and recovery of tree-island communities that are degraded during extreme high water events.

Problem Addressed

As illustrated in the Everglades sloughs conceptual model, water management practices have generated hydrologic stress on the system in the form of regulatory releases and shortened hydroperiods. The ecologic response to this stress includes flooded tree islands and alligator nests, soil subsidence, spread of exotic vegetation, and ultimately the degredation of plant community structure and the reduction in numbers of native fauna. The extreme events performance measures assess the frequency and duration of water levels that exceed values associated with two major sources of ecological damage in the slough/sawgrass/peat system, namely, muck fires and microbial oxidation during extreme low-water events, and death of tree-island organisms during prolonged high water.

Model Target

Target values for extreme events in LNWR were 1995 Base values, in keeping with the refuge's current regulation schedule. The high water performance target for all other indicator regions in the Northern and Central Everglades was that the number and duration of events be less than or equal to NSM values. For low water extremes, the performance target was to minimize frequencies and duration of events.

Model Output Format

The extreme events measures assess the frequency and duration, for different alternatives, of periods of extreme high and low water. The basic variable calculated is the number of weeks during the period of record during which water levels exceeded a criterion high or low, and the average duration of these events. These counts are obtained for each cell within an indicator region, and then averaged over the cells in the region to obtain an average number of extreme events and an average duration of these events for the entire period of record for that indicator region. Results are presented in tabular form.

Evaluation Tools

Output from the South Florida Water Management Model and the Natural System Model 4.5 for the following indicator regions is used: (groupings correspond to areas with distinct hydrologic performance.)
Loxahatchee NWR (Indicator Regions 26 & 27)
Holey Land & Rotenberger WMAs (Indicator Regions 28 & 29)
WCA-2A (Indicator Regions 24 & 25)
WCA-2B (Indicator Region 23)
NW WCA-3A (N of Alligator Alley & W of Miami Canal; Indicator Regions 20 & 22)
Northeastern WCA-3A (N of Alligator Alley & E of Miami Canal; Indicator Region 21)
Eastern WCA-3A (S of Alligator Alley, E of Miami Canal; Indicator Region 19)
Central & Southern WCA-3A (S of A. Alley, W of Miami Canal; Indicator Regions 14, 17 & 18)
9. WCA-3B(Indicator Regions 15 & 16)
10. Pennsuco Wetlands (Indicator Regions 52 & 53)

Water Supply/Resource Protection

Performance Measure

Preventing Salt-Water Intrusion of the Biscayne Aquifer: Stage Duration Curves for selected control structures

Date Submitted/Revised

May 1998

General Planning Objective

Minimum Flows and Levels – SFWMD; Control salt-water intrusion into freshwater aquifers – GCSSFL; Ensure adequate water supply and flood protection for urban, natural and agricultural needs – GCSSFL

Region

Lower East Coast Service Area 3– Eastern portions Miami-Dade County

Restoration Goal

Prevent further encroachment of salt-water interface into the Biscayne aquifer in South Miami-Dade County. Evaluation methodology described herein is to facilitate evaluation and comparison of alternatives and not to supplant the research and analysis necessary to determine the control elevations to slow salt-water intrusion.

Problem Addressed

The principal threat to the maintaining the long-term functions of the Biscayne aquifer is salt-water intrusion, i.e. contamination of the aquifer by saltwater. The Biscayne aquifer is located along the eastern edge of Palm Beach County, underlies the majority of Broward County and almost all of Miami-Dade

County. Along the aquifer's eastern edge, its fresh water is in contact with the salt water originating from the ocean. The constant westerly flow of fresh water from the Everglades helps to keep the salt water stationary. However, when groundwater levels adjacent to the fresh water/salt water interface are lowered, salt water can potentially move inland replacing the fresh water (Swift *et al*. 1998). The higher density salt water tends to remain inland for long periods of time causing a permanent loss of that portion of the aquifer. Along the Lower East Coast, lowering of the groundwater table due to overdrainage and increased well field withdrawals has allowed salt water to invade and contaminate the Biscayne aquifer during periods of drought (Parker *et al*. 1955). Salt water intrusion of the Biscayne aquifer is considered one of the greatest threats to the long-term water supply of South Florida.

In order to minimize the inland migration of the saline interface, a sufficient head of fresh water must be maintained within the aquifer. Loss of the fresh water head that previously existed west of the Atlantic Coastal Ridge is considered the primary cause of the inland migration of salt water in South Florida (Parker et al. 1955; Fish and Stewart, 1991). The groundwater hydrology of South Florida's Lower East Coast has been permanently altered by urban and agricultural development and construction of the Central and Southern Florida Project. Construction of a series of canals has drained both the upper layer of the Biscayne aquifer and the fresh water mound west of the Atlantic Coastal Ridge. This drainage has reduced the volume of groundwater flowing east and has resulted in the inland migration of saline interface along the entire edge of the aquifer during dry periods. Localized saltwater intrusion has resulted from large coastal wellfields, five of which were partially lost in1939 while others are still threatened today. Construction of coastal canal water control structures, beginning in the 1940s, has helped to stabilize or slow the advance of the saline interface.

Water levels in the coastal canals largely govern the expected inland migration of the saline interface. Managing coastal canals at appropriate water levels during drought periods is a viable option for stabilizing the salt water interface and preventing further inland migration (Swift et al. 1998). The control elevations have been set for the primary canals that receive water from the regional system and have sufficient canal conveyance capacity to receive water from outside their drainage basins.

At this time, salt-water intrusion criteria do not exist for the major canals in southern Miami-Dade County. Generally the canals are cut directly into the most pereable portions of the Biscayne aquifer. It is difficult to maintain canal stages for extended periods of time without using significant volumes of water from regional storage. However, it is important to evaluate water levels in these canals because encroachment of the salt front into the Biscayne aquifer has occurred previously in this area. Plus, major public water supply wellfields are located in southern

Miami-Dade County. This area was evaluated by using the stage duration curves for the following structures: C-100A @ S-123, C-1 @ S-21, C-102 @ S-21A, and C-103 @ S-20F. The stage duration curves were used to evaluate the alternatives in two ways: 1) the distance by which an alternative's water level fails to reach two feet NGVD at the 90th percentile of the stage duration curve; and 2) the percentile at which an Alternative's stage duration curve meets the 50th percentile of the 1995 Base's stage duration curve.

In the first scenario, two feet NGVD was used for comparison in keeping with the Ghyben-Herzberg relationship which estimates that one foot of freshwater head is required to protect forty feet of aquifer. The aquifer along the coast in southern Miami-Dade is approximately eighty feet that would require two feet of freshwater head. The 90th percentile of the stage duration curve was used since that percentile reflects lower stages of the dry season when the risk of salt-water intrusion is increased. The score is calculated from the distance of the base conditions and alternatives to the two feet NGVD on the stage duration curve. Alternatives that equaled or exceeded the target scored 100% (no extra credit was given for exceeding the target).

Score = [(2 - Distance/2)] x 100 = % of meeting 2 foot target

The second scenario used the 50th percentile of the 1995 Base to evaluate performance since it represents approximately the midpoint between the wet and dry seasons and can be viewed as "average conditions" for the 1995 Base. The score reflects the percentile at which a base condition or alternative meets or exceeds the water level at the 50th percentile of the 1995 Base. Salt-water encroachment has occurred in the period of record and, therefore, exceeding the 50th percentile is considered an improvement but may not prevent further encroachment.

Model Target

Maintain elevations of primary coastal canals at control structures. These targets are the current operational criteria. The canal stages need to be examined further to develop appropriate targets and operation criteria to prevent encroachment of the salt water into the surficial aquifer.

Canal - Structure	Canal Stages (ft NGVD)
C-100A@ S-123	2.00
C-1@ S-21	2.00
C-102 @ S-21A	2.00
C-103 @ S-20F	2.00

Model Output Format

Model Output Format: Stage Duration Curves for four control structures: C-100A@S-123, C-1@S-21, C102@S21A and C-103@20F

Evaluation Tools

Use output from the south Florida Water Management Model

Performance Measure

Seasonal Distribution of Overland Flow Volume, Mid Shark River Slough

Date Submitted/Revised

June 1988

General Planning Objective

This performance measure is linked to the Everglades Sloughs Conceptual Model developed by the SERA Natural Systems Team, and addresses several hydrologic and ecologic planning objectives identified by the Governors's Commission for a Sustainable South Florida in the C&SF Project Restudy Conceptual Plan.

Region

The seasonal distribution of overland flow volume is applied as a performance measure only to the cross section in mid Shark River Slough.

Restoration Goal

The re-distribution of flow into Shark River Slough, with subsequent restoration of extended duration of uninterrupted flooding, brief duration of dry conditions, water depth pattern, and overland flow volume and **timing characteristic** of the pre-drainage system is among the highest priorities of ecosystem restoration in the southern Everglades.

Problem Addressed

Restoration of the seasonal timing of flow down Shark River Slough is important to extend the duration of flooding in the Slough and to provide seasonal salinity patterns in the estuaries as they would have occurred in the natural system

Model Target

The target is a cumulative deviation that does not exceed that indicated by NSM45F.

Model Output Format

The overland flow volume across the cross-section in mid Shark River Slough that occurs each month of the year is calculated as the percent of the annual flow volume and is averaged over the 31-year period of record. The performance measure is the cumulative deviation of the monthly percent of annual flow under a given alternative from the monthly percent of flow under NSM45F, summed over the 12 months of the year. It is given a weighting of one when averaged with the other performance measures for Shark River Slough because of the higher level of uncertainty in NSM45F simulations of flow compared to other parameters.

Evaluation Tools

The South Florida Water Management Model and Natural System Model should be used to evaluate a cross section evaluate a cross-section taken across the entire width and depth of flow in mid Shark River Slough.

Ecological

Performance Measure

Duration of Uninterrupted Flooding

Date Submitted/Revised

June 1998

General Planning Objective

The duration of uninterrupted flood events is the highest priority hydrologic performance measure for ecological restoration in the Everglades. Conceptual models of both the ridge and slough landscapes and the marl prairie/rocky glades landscapes identify duration of uninterrupted flooding as the single hydrologic parameter that affects all the plant and animal attributes that are considered to be indicators of ecological health in the Everglades.

Region

Duration of uninterrupted flooding is applied as a performance measure to the Shark River Slough. and Rockland Marl Marsh (Indicator regions 8, 9, 10, and 11).

Restoration Goal

Increased nesting success and abundance of American alligators and a corresponding increase in the number of occupied alligator holes to serve as drought refugia and to increase habitat heterogeneity, 2) increased population density of aquatic fauna, 3) increased abundance of wading birds and wood storks, 4) re-establishment of coastal nesting colonies of wading birds and wood storks, 5) delay (syn) in timing of colony formation by wading birds and wood storks, 6) resumption of the return frequency of wading bird and white ibis super colonies, 7) enhanced production and community composition of periphyton, 8) accelerated accretion of marl and peat soils, 9) persistence and resilience of macrophyte and tree island plant communities including the cessation of sawgrass expansion into wet prairies and sloughs, and 10) increased nesting success and population size of Cape Sable seaside sparrows.

Problem Addressed

Due to water management practices, inundation frequency and duration in Shark River Slough and the Rockland Marl Marsh landscapes have been altered from pre-drainage patterns. The re-distribution of flow into Shark River Slough, with subsequent restoration of extended duration of **uninterrupted flooding**, brief duration of dry conditions, water depth pattern, and overland flow volume and timing characteristic of the pre-drainage system is among the highest priorities of ecosystem restoration in the southern Everglades.

Model Target

The target is the mean duration of flooding indicated by NSM45F.

Model Output Format

Only flood events when the mean water depth equals or exceeds 0.2 feet are measured because depths less than 0.2 feet have been observed to impair the establishment of populations of aquatic organisms. The mean duration of all such flood events during the 31-year period of record is the performance measure. It is given a weighting of 3 when averaged with the other performance measures for these regions.

Evaluation Tools

The South Florida Water Management Model and Natural System Model should be used to evaluate Indicator Regions:

Rockland Marl Marsh
SW Shark Slough
Mid Shark Slough
NE Shark Slough

Ecological

Performance Measure

Duration of Dry Conditions

Date Submitted/Revised

June 1998

General Planning Objective

The re-distribution of flow into Shark River Slough, with subsequent restoration of extended duration of uninterrupted flooding, **brief duration of dry conditions**, water depth pattern, and overland flow volume and timing characteristic of the pre-drainage system, is among the highest priorities for ecosystem restoration in the southern Everglades. The conceptual models identify drought severity as the second most important hydrologic variable for ecological restoration in the Everglades.

Region

The mean duration of dry events is applied as a performance measure to the Shark River Slough and Rockland Marl Marsh indicator regions.

Restoration Goal

Increased nesting success and abundance of American alligators and a corresponding increase in the number of occupied alligator holes to serve as drought refugia and to increase habitat heterogeneity, 2) increased population density of aquatic fauna, 3) increased abundance of wading birds and wood storks, 4) re-establishment of coastal nesting colonies of wading birds and wood storks, 5) delay (syn) in timing of colony formation by wading birds and wood storks, 6) resumption of the return frequency of wading bird and white ibis super colonies, 7) enhanced production and community composition of periphyton, 8) accelerated accretion of marl and peat soils, 9) persistence and resilience of macrophyte and tree island plant communities including the cessation of sawgrass expansion into wet prairies and sloughs, and 10) increased nesting success and population size of Cape Sable seaside sparrows.

Problem Addressed

Drought severity affects the ability of aquatic fauna to survive dry conditions in alligator holes and solution holes, the intensity of wild fires, and the loss of peat soil in the Everglades.

Model Target

Mean duration of dry events indicated by NSM45F

Model Output Format

Drought severity is most clearly indicated by 2X2 model output as the duration of dry conditions. Dry events are defined as times when the water level drops either to zero or a negative value below the ground surface. Two dry events that are separated by a flood event when the water level rises to less than 0.2 feet above the ground surface are grouped as one dry event because such a minor flood event has been observed to impair the establishment of populations of aquatic organisms. In that case, the duration of the dry event is calculated as the sum of the two dry events and the intermittent flood event. The performance measure is the mean duration of all dry events during the 31-year period of record. It is given a weighting of two when averaged with the other performance measures for these regions.

Evaluation Tools

The South Florida Water Management Model and Natural System Model should be used to evaluate Indicator Regions:

Rockland Marl Marsh
SW Shark Slough
Mid Shark Slough
NE Shark Slough

Ecological

Performance Measure

Mean Depth During Flooding

Date Submitted/Revised

June 1998

General Planning Objective

The water mean depth during periods of flooding was identified in the Everglades Sloughs Conceptual Model as relevant to the community composition of wetland vegetation, to the establishment, survival and community composition of aquatic fauna, and to the freshwater head driving flows toward Florida Bay. While the mean depth during flooding is important in these regards, it is not considered to be as high a priority in the restoration of ecological values as duration of flooding or drought severity in the southern Everglades

Region

The mean depth during flooding is applied as a performance measure only to Shark River Slough (Indicator Regions 9, 10 and 11).

Restoration Goal

Increased nesting success and abundance of American alligators and a corresponding increase in the number of occupied alligator holes to serve as drought refugia and to increase habitat heterogeneity, 2) increased population density of aquatic fauna, 3) increased abundance of wading birds and wood storks, 4) re-establishment of coastal nesting colonies of wading birds and wood storks, 5) delay (syn) in timing of colony formation by wading birds and wood storks, 6) resumption of the return frequency of wading bird and white ibis super colonies, 7) enhanced production and community composition of periphyton, 8) accelerated accretion of peat soils, 9) persistence and resilience of macrophyte and tree island plant communities including the cessation of sawgrass expansion into wet prairies and sloughs.

Problem Addressed

Shark River Slough represents the largest drainage basin in the southern Everglades and contains most of the ridge and slough peatland landscape within Everglades National Park. Pre-drainage Shark River Slough was the classic river of grass, a nearly continuously flowing and flooded peatland. Multi-year periods of flooding in Shark River Slough, punctuated by infrequent and brief dry conditions, provided a year-round aquatic ecosystem that produced peat deposits, drove the hydrology of adjacent rockland and marl marshes, provided a drought refugium for aquatic organisms from the adjacent shorter-hydroperiod wetlands, and influenced the salinity regimes in the coastal basins of Florida Bay. The re-distribution of flow into Shark River Slough, with subsequent restoration of extended duration of uninterrupted flooding, brief duration of dry conditions, **water depth pattern**, and overland flow volume and timing characteristic of the pre-drainage system, is among the highest priorities for ecosystem restoration in the southern Everglades.

Model Target

The target is the mean depth indicated by NSM45F.

Model Output Format

To be consistent with the definition for the duration of flooding, only events when the water depth averaged at least 0.2 feet are included in the calculation. The performance measure is the mean depth of all flood events during the 31-year period of record. It is given a weighting of one when averaged with the other performance measures for Shark River Slough.

Evaluation Tools

The South Florida Water Management Model and Natural System Model should be used to evaluate Indicator Regions:

SW Shark Slough
Mid Shark Slough
NE Shark Slough

Ecological

Performance Measure

Wet Season Water Level Reversals

Date Submitted/Revised

June 1998

General Planning Objective

This performance measure is linked to the Marl Prairie/Rocky Marl Marsh Conceptual Model developed by the SERA Natural Systems Team, and addresses several hydrologic and ecologic planning objectives identified by the Governors's Commission for a Sustainable South Florida in the C&SF Project Restudy Conceptual Plan.

Region

The number of wet season reversals is applied as a performance measure only to the Rockland Marl Marsh, since reversals were not found to apply to Shark River Slough in the model outputs

Restoration Goal

Recover natural system pattern of wet season reversals.

Problem Addressed

A wet season water level reversal is defined as an incident during a period of flooding when water depth recedes to less than 0.2 feet, but then rebounds to greater than 0.2 feet, without the marsh drying completely. A reversal is distinguished from a dry period in that during a reversal, water depth does not drop to or below the ground surface The Marl Prairie/Rocky Glades Conceptual Model identifies a critical ecological pathway triggered when water depth drops to less than 0.2 feet during a period of flooding; aquatic fauna population densities decline, survivors retreat to refugia in solution holes or alligator holes, and population recovery is slowed

Model Target

The target is not to exceed the number of reversals indicated by NSM45F.

Model Output Format

The performance measure is the total number of reversals during the 31-year period of record. It is given a weighting of one when averaged with the other performance measures for the Rockland Marl Marsh.

Evaluation Tools

The South Florida Water Management Model and Natural System Model should be used to evaluate the Rockland Marl Marsh (Indicator region 8)

Ecological

Performance Measure

Total Annual Overland Flow Volume, Mid Shark River Slough

Date Submitted/Revised

June 1998

General Planning Objective

This performance measure is linked to the Everglades Sloughs Conceptual Model developed by the SERA Natural Systems Team, and addresses several hydrologic and ecologic planning objectives identified by the Governors's Commission for a Sustainable South Florida in the C&SF Project Restudy Conceptual Plan.

Region

The total annual overland flow volume is applied as a performance measure only to a cross section in mid Shark River Slough.

Restoration Goal

The re-distribution of flow into Shark River Slough, with subsequent restoration of extended duration of uninterrupted flooding, brief duration of dry conditions, water depth pattern, and **overland flow volume** and timing characteristic of the pre-drainage system.

Problem Addressed

The annual overland flow volume down Shark River Slough provides a measure of the total contribution of the Slough to freshwater inputs to the Gulf of Mexico and Florida Bay estuaries. Flow volume also relates to duration of flooding and water depth within the Slough..

Model Target

The target is the annual overland flow volume indicated by NSM45F.

Model Output Format

The monthly volumetric flow rate is simulated as the volume passing a section perpendicular to the direction of flow. The cross-section is taken across the entire width and depth of flow in mid Shark River Slough. The total annual flow volume is determined by summing the monthly flow values. The total annual flow volume is averaged over the 31-year period of record. The performance measure is the mean annual flow volume expressed as percent of the NSM45F flow volume. It is given a weighting of one when averaged with the other performance measures for Shark River Slough because of the higher level of uncertainty in NSM45F simulations of flow compared to other parameters

Evaluation Tools

The South Florida Water Management Model and Natural System Model should be used to evaluate a cross-section taken across the entire width and depth of flow in mid Shark River Slough.

Performance Measure
Salt Intrusion Front Movement and Groundwater Flows to Biscayne Bay

Date Submitted/Revised
August, 1998

General Planning Objective

This measure addresses Governor's Commission for a Sustainable South Florida general planning objectives: 1) Restore more natural hydropatterns, including associated sheetflow, and 2) Provide more natural quality and quantity, timing and distrubutuion of freshwater flow to and through the natural Everglades

Region

This performance measure addresses groundwater flows into Biscayne Bay and affects LEC Service Area 3

Restoration Goal

The restoration target is to restore, to the extent possible, the hydraulic head which drives groundwater flows to Biscayne Bay. Preliminary analysis of the existing Miami-Dade County water quality database for Biscayne Bay indicates that some groundwater flows may occur during periods of high rainfall or during wet years. This is an indication that it may be possible to increase groundwater flows to the bay by raising watershed groundwater levels to the extent possible without triggering flood control measures.

Problem Addressed

Biscayne Bay historically received a large portion of its freshwater inputs from groundwater. Groundwater seeps and springs were/are located throughout the bay and historically, freshwater entered the bay in a more or less distributed manner. Drainage of the watershed for flood control lowered regional groundwater levels and reduced the hydraulic head west of the Atlantic Coastal Ridge which drove these flows. The result has been a reduction in the freshwater inputs from groundwater and an increase in the proportion of the freshwater budget which is provided through surface water flows from the canals. The current surface water flows constitute a point source discharge and although the freshwater is required to maintain estuarine conditions, the distribution and timing of the point source discharges cause large local variations in salinity which are harmful to marine and estuarine biota.

Model Target

The following target groundwater levels, which are based on the Ghyben-Herzberg relationship, would therefore represent the direction in which groundwater levels need to be raised in order to create a more desirable hydraulic head for driving increased groundwater flows to Biscayne Bay. Alternatives that improve conditions over base or future base (i.e. where the groundwater levels more closely approach the Ghyben-Herzberg relationship) are preferable to those where conditions are equal to or worse than base or future base. It should be noted that direct comparisons of target groundwater levels calculated with the Ghyben-Herzberg relationship and the LEC Minimum Levels should not be made. The LEC Minimum Levels are for canal stages at the specified structures; the groundwater levels for the surrounding land will be higher.

Cell Cluster	Approximate Depth to the Base of the Biscayne Aquifer *	Target Groundwater Levels based on the Ghyben-Herzberg Relationship	Average Topography for Cell Cluster (from Topography for SFWMM)	LEC Minimum Flows and Levels - Canal/Structure
North Bay #1	180 ft. between G-3300 and the Snake Creek (C-9) Canal	4.5 NGVD	9.61 NGVD	2.00 - C-9/S-29
North Bay #2	130 ft. at mouth of the Miami Canal	3.25 NGVD	8.25 NGVD	2.50 - C-6/S-26
Central Bay	110 ft. at Snapper Creek	2.75 NGVD	10.26 NGVD	2.50 - C-2/S-22
South Bay	85 ft. at G-3316	2.13 NGVD	5.1 NGVD	None Set

Source: Fish, J.E. and M. Stewart 1991. Hydrogeology of the Surficial Aquifer System, Dade County, Florida. U.S. Geological Survey Water Resources Investigations Report 90-4108, 50 pp.

Model Output Format

Area of Interest: Four blocks of WMM model cells distributed along the western shoreline of Biscayne Bay. The cell clusters are as follows:
North Bay Block #1: R28, C36; R27, C36; R27, C35; R26, C35
North Bay Block #2: R24, C34; R23, C34

Central Bay Block: R21, C33; R20, C33; R20, C32; R19, C32; R19, C31
South Bay Block: R14, C30; R13, C30; R12, C30; R12, C29

North Bay #1 is centered over the Atlantic Coastal Ridge, is bisected by the Biscayne (C-8) Canal, and is composed predominantly of higher elevation uplands. North Bay #2 is centered over the Miami River but intersects the Atlantic Coastal Ridge at the extreme north and south ends, and therefore is composed predominantly of moderate to low-lying uplands. Central Bay Block is centered over the Snapper Creek (C-6) Canal and is composed predominantly of higher elevation uplands. South Bay Block is located between Cutler Ridge and the north end of the Model Lands Basin and is composed almost entirely of low-lying uplands and wetlands.

Groundwater stage hydrographs (weekly averages) and groundwater stage duration curves over the period of record, averaged for each of the cell blocks. Average elevation for each cluster and the Ghyben-Herzberg relationship for that location (based on the aquifer depth at that location - provided below) should be displayed as horizontal lines superimposed on the hydrographs and stage duration curves. Although similar to the salt intrusion performance measures for the LEC, this measure is different because it looks at area groundwater levels rather than canal stages.

Bar graph showing the number of times weekly average groundwater levels equal or exceed the Ghyben-Herzberg relationship for that cell block over the period of record. Alternatives with higher numbers of events would provide higher groundwater flows to Biscayne Bay than alternatives with lower numbers or no events.

Although more appropriate for a static aquifer, the Ghyben-Herzberg relationship (depth to the saltwater interface (below sea level) in a coastal aquifer is 40 times the elevation of the water table above sea level at the same location) can be used as a first approximation for the groundwater levels necessary to maintain freshwater conditions to the base of the aquifer. The LEC Water Supply Plan Committee proposed minimum canal stages for the C-9, C-6, and C-2 to prevent salt intrusion to the Biscayne Aquifer, but modified the levels projected by this relationship based on information that the equation would overestimate the head needed in a flowing system (SFWMD 1997).

Flood Control

Performance Measure

End of Month Stage Duration Curve1983-1993

Date Submitted/Revised

February, 1998

General Planning Objective

This performance measure addresses the general planning objective identified by the Governor's Commission for a Sustainable South Florida in the Conceptual Plan for the C&SF Project; establish levels of provided flood protection in terms of frequency, depth, and duration

Region

C-111 Basin

Restoration Goal

Provide flood protection to the area east of the L-31N and C-11 canals and south of Richmond Drive.

Problem Addressed

The property east of the L-31N and C-111 canals, south of Richmond Drive, was provided a beneficial level of flood protection during the 1983 to 1993 period by the way those two canals were operated. During that period, water levels were raised during the dry months without causing increased water levels during the wet periods. Limited data from 1994-1996 indicate that Experimental Water Deliveries

Program tests 6 and 7 have not achieved this objective. Farmers in the area have experienced a decreased ability to eliminate excess stormwater from their fields.

An occurrence of ground water stage within two (2) feet of the ground surface for a duration of greater than 24 hours is considered a flood event with the potential for causing agircultural crop loss. The SFWMM has no capability to directly measure flood control on individual fields or during relatively short events. Peak stage difference maps have been developed to provide a general indication of the estimated changes in simulated peak stages that result from an alternative scenario. They cannot be used as a performance measure for changes in flooding risk at a particular location for a specific storm event.

Model Target

The 1983-93 portion of the stage duration curve taken from the model calibration and validation runs for each of the five (5) indicator cells in the southern Dade area.

Model Output Format

Stage duration curve described above.

Ecological

Performance Measure

Daily Hydrograph with Spring Water Recession Windows

Date Submitted/Revised

January 14, 1998

General Planning Objective

This performance measure addresses one of the preferred options for ecosystem restoration of the Lake Okeechobee Area identified by the Governor's Commission for a Sustainable South Florida; to restore more natural fluctuations of lake levels with no significant impacts to the littoral zone. It also addresses several general planning objectives identified in the conceptual plan for the C&SF Project Restudy; improve habitat quality and heterogeneity, and restore more natural hydropatterns.

Region

Lake Okeechobee

Restoration Goal

Optimize intra-year variation in lake levels to provide a healthy ecosystem for wading birds and other wildlife.

Problem Addressed

Research conducted in the comprehensive Lake Okeechobee Ecosystem Study (LOES) indicated that a certain degree of seasonal variation in lake levels is necessary to maintain a healthy ecosystem (Aumen and Wetzel 1995). In particular, studies dealing with wading bird nesting and food resource (forage fish) utilization indicated that a spring (January through May) recession in lake levels from near 15 ft to below 12 ft, with no reversal greater than 0.5 ft during that period, would optimize the health of those animal populations (Smith et al. 1995, Smith and Callopy 1995). Receding lake levels in spring serve to concentrate prey resources at a time when birds are searching for food for their offspring. Avoiding reversals during that time period is critical, because birds select nesting sites on the basis of current lake levels, and their sense of where lake levels are going in the future. Reversals (sudden increases in lake level following a period of decline) are unexpected events that can flood out and destroy nests. Reversals also can interfere with the reproductive cycle of other animals (e.g., the apple snail) which lay eggs on emergent plant stems. Spring lake level recessions to below 12 ft also benefit the ecosystem by invigorating willow stands (a critical nesting habitat for wood stork) and allowing fires to burn away cattail thatch.

Model Target

The general goal is to achieve a hydropattern for the lake that results in as many years as possible with spring lake level recessions falling within the "windows" of the performance indicator graph. However, it is unclear how many total years out of 30 would be the ideal case.

Model Output Format

A 30-year daily stage hydrograph for the 1995 and 2050 base conditions and each water supply Alternative, overlaid by "windows" spanning the 12-15 ft depth and Jan-May seasonal ranges.

Ecological

Performance Measure

Similarity in Duration of Lake Stages >15 ft

Date Submitted/Revised

January 14, 1998

General Planning Objective

This performance measure is linked to the Lake Okeechobee Conceptual Model.

It addresses the general planning objective, improve habitat quality and heterogeneity, identified in the conceptual plan for the C&SF Project Restudy.

Region

Lake Okeechobee

Restoration Goal

Minimize the frequency of prolonged events (lake stages exceed 15 ft for more than 12 continuous months) that may limit light penetration to the lake bottom .

Problem Addressed

Prolonged moderate high lake levels (>15 ft) are harmful to the lake's ecological and societal values, including the recreational fishery, birds and other wildlife, the native vegetation mosaic, recreation, ecotourism and water quality (Havens and Rosen 1997). Such events result in loss of submerged plant communities due to light limitation (Steinman et al. 1998), increase the lake-wide phosphorus concentrations (Havens 1998), and may cause an increased frequency of algal blooms in near-shore areas (Maceina 1993).

Model Target

The objective is to avoid prolonged high water level conditions that result in the adverse impacts described above, in order to protect the lake's ecological and societal values. From the standpoint of these objectives, the optimal output would be a "box" spanning the range from approximately 0 to 90 days (3 months), and "whiskers" not reaching beyond 180 days (6 months).

Model Output Format

"Box-whisker" plots showing duration statistics (median, maximum, minimum, 25 and 75th percentile duration in days) for lake stages in excess of 15 ft for a historic period, the 1995 and 2050 base cases, and each proposed water supply Alternative for the 30 year period of record. Each lake regulation schedule alternative will be compared to the period of historical record (1950-1972).

Performance Measure
Similarity in Duration of Lake Stages <12 ft.

Date Submitted/Revised
January 14, 1998

General Planning Objective

This performance measure is linked to the Lake Okeechobee Conceptual Model.

It addresses the general planning objective, improve habitat quality and heterogeneity, identified in the conceptual plan for the C&SF Project Restudy.

Region
Lake Okeechobee

Restoration Goal

Minimize the frequency of prolonged events (lake stage falls below 12 feet for longer than 12 continuous months) that substantially reduce the littoral area available as wildlife habitat, and promote exotic plant expansion.

Problem Addressed

Prolonged moderate low (<12 ft) lake levels are harmful to the lake's ecological and societal values, including the recreational fishery, birds and other wildlife, the native vegetation mosaic, recreation, ecotourism and water quality (Havens and Rosen 1997). At lake levels below 12 ft, over 70% of the marsh is dry, and cannot function as a habitat for fish, birds or other wildlife (SFWMD 1997). These conditions also are favorable for expansion of exotic plants into native plant-dominated regions of the marsh (Thayer and Haller 1990, Lockhart 1995).

Model Target

The objective is to avoid prolonged low water level conditions that result in the adverse impacts described above, in order to protect the lake's ecological and societal values. From the standpoint of these objectives, the optimal output would be a "box" spanning the range from approximately 0 to 90 days (3 months), and "whiskers" not reaching beyond 180 days (6 months).

Model Output Format

"Box-whisker" plots showing duration statistics (median, maximum, minimum, 25 and 75th percentile durations in days) for lake stages below 12 ft for a historic period, the 1995 and 2050 base cases, and each proposed water supply Alternative for the 30 year period of record. of each lake regulation schedule alternative will be compared to the period of historical record (1950-1972).

Performance Measure
Similarity in Duration of Lake Stages <11 ft

Date Submitted/Revised
January 14, 1998

General Planning Objective
This performance measure is linked to the Lake Okeechobee Conceptual Model.

It addresses the general planning objective, improve habitat quality and heterogeneity, identified in the conceptual plan for the C&SF Project Restudy.

Region
Lake Okeechobee

Restoration Goal
Minimize the frequency of extremely low lake stages (<11 ft) that result in a loss of the littoral zone as habitat for aquatic biota, and promote expansion of exotic plants into pristine native-plant dominated regions of the lake.

Problem Addressed
Extreme low lake levels (<11 ft), of any duration, are harmful to the lake's ecological and societal values, including the recreational fishery, birds and other wildlife, the native vegetation mosaic, recreation, ecotourism and water quality (Havens and Rosen 1997). Low lake levels dry out critical marsh habitat, and may permit the more rapid expansion of exotic plants (*Meleleuca* and torpedo grass) into regions still occupied by native plant communities (Thayer and Haller 1990, Lockhart 1995). At lake levels 11 ft, nearly 95% of the littoral zone is dry, including the Mooneshine Bay region. This region is of particular concern, since it is a prime habitat for snail kite, and a last refuge for these federally-endangered birds (as well as other species) during regional droughts (Bennetts and Kitchens 1997). At present, Moonshine Bay is an excellent habitat because it is dominated by spike rush (*Eleocharis*) and bladderwort (*Utricularia*), which provide considerable open-water habitat for forage fish, and substrates for apple snail eggs. If the region should be overtaken by torpedo grass, whose expansion into new areas appears to be hindered by standing water (Thayer and Haller 1990), these habitat values could be lost.

Model Target
The objective is to avoid the extreme low water level conditions that result in the adverse impacts described above, in order to protect the lake's ecological and societal values. From the standpoint of these objectives, the optimal output would be no such events; i.e., all attributes of the box-whisker plot below zero.

Model Output Format
"Box-whisker" plots showing duration statistics (median, maximum, minimum, 25 and 75th percentile durations in days) for a historic period, the 1995 and 2050 base cases, and each proposed water supply Alternative for the 30 year period of record. of each lake regulation schedule alternative will be compared to the period of historical record (1950-1972).

Ecological

Performance Measure

Similarity in Duration of Lake Stages >17ft

Date Submitted/Revised

January 14, 1998

General Planning Objective

This performance measure is linked to the Lake Okeechobee Conceptual Model.

It addresses the general planning objective, improve habitat quality and heterogeneity, identified in the conceptual plan for the C&SF Project Restudy.

Region

Lake Okeechobee

Restoration Goal

Minimize the frequency of extreme high lake stage events (>17ft) that may cause wind and wave damage to the shoreline plant communities, and transport phosphorus-laden pelagic water into pristine interior regions of the littoral zone.

Problem Addressed

When lake levels reach this extreme high, the following impacts can be expected, in addition to those occurring when lake levels exceed 15 ft; damage to bulrush and other shoreline plant communities by wind and waves, and transport of nutrients into the pristine littoral marsh, with nutrient-induced changes in periphyton, plant, and animal communities

Model Target

The goal is to have zero events.

Model Output Format

"Box-whisker" plots showing duration statistics (median, maximum, minimum, 25 and 75th percentile durations in days) for a historic period, the 1995 and 2050 base cases, and each proposed water supply Alternative for the 30 year period of record. Each lake regulation schedule alternative will be compared to the period of historical record (1950-1972).

Water Supply

Performance Measure

Agricultural and urban water supply using the Monthly Supply-Side Management Report and Simulated Annual Demands not Met per Year (for each coastal service area).

Date Submitted/Revised

January 1998

General Planning Objective

Soon after the C&SF Comprehensive Review Study (Restudy) process was initiated, SFWMD's Lower East Coast Regional Water Supply Plan staff made a decision to defer planning and making recommendations on phase 2 water supply projects due to potential conflicts with the Restudy results. The phase 2 projects are needed primarily to address environmental goals and agricultural water supply needs that were not met by the LEC WSP projects proposed in phase 1 of the plan. Subsequent to that decision, WRDA 1996 shortened the time period in which the Restudy would be conducted. In 1997, the Florida Legislature modified Florida law

(HB 715) and included some clarification of how the Water Management Districts were to do water supply planning. The Districts' regional water supply plans now must contain a "level-of-certainty planning goal associated with identifying the water supply needs of existing and future reasonable-beneficial uses shall be based upon meeting those needs for a 1-in-10 year drought event" (Chapter 373.0361(2)(a)(1), F. S.). Since a portion of SFWMD's water supply planning was deferred and is now taking place in the Restudy process, it's expected that the goal stated in Florida law be adopted as the Restudy goal.

Region

The Lake Okeechobee Service Area includes the Everglades Agricultural Area, the Caloosahatchee Basin, the St. Lucie Basin, the S-4 Basin, the L-8 Basin and the Seminole Indian (Brighton and Big Cypress) Reservations

Restoration Goal

Water shortage restrictions for the Lake Okeechobee Service Area should be limited to not more than three in the 31-year simulation period.

Problem Addressed

Chapter 373.246, F.S., requires that the Water Management Districts develop a water shortage plan to protect the water resources from serious harm during droughts, and to restore them to their previous condition. In the present water shortage rule, cutbacks in water usage are triggered by either a saltwater intrusion event (well triggers) or by a low-Lake-Okeechobee event. The regional system is operated so that deliveries to the coast are made to either halt or slow down saltwater intrusion. Deliveries are made first from the Water Conservation Areas, then from Lake Okeechobee, depending on what their respective water levels are and on what basin is experiencing the shortage. Under the water shortage plan, provisions for variances and alternative measures to prevent undue hardship and ensure equitable distribution of water resources may be included.

With the present configuration of the C&SF System, Lake Okeechobee is the only reliable water supply source of significance during extended droughts. The Lake Okeecheebee Supply-Side Management Plan was designed to establish a procedure for supply allocation during periods of shortage. The allocation method that was developed recognized the need to hold water in reserve for anticipated high-demand periods, and recognized the actual physical limitations of the delivery system. Water supply releases during dry periods are determined by a set of water shortage management zones. Each of the zones represents storage levels with assigned probabilities of shortage. Some of the assumptions of the original methodology are: 1) that a stage of 13.5 ft on October 1 as being the level which must be exceeded to defer supply-side management; and 2) water deliveries from the Lake would be based on a weekly formula that allocated the available water in the Lake above a stage of 11 feet. The Governing Board would decide each month on additional steps necessary to manage available supplies during the shortage.

The volume of water between 11 ft and 10 ft. is reserved for the purpose of preventing saltwater intrusion in the Lower East Coast wellfields. Because of downstream physical limitations, water cannot be removed from the lake when it falls below 9.5 ft. These operational rules are being used in the SFWMM model runs for the Restudy alternatives.

A second issue that adds to the difficulty of defining “1 in 10” is deciding what to assume the effect of implementing minimum flows and levels (MF&Ls) will be on how the regional system will be operated. There is potential the water shortage plan and supply-side management plan could be modified, depending on how future policy and legal decisions are made. If the outcome of future minimum flow and level-related rule development, lawsuits, changes to current law, require the operational rules of the regional system to be changed from what is assumed in the Restudy, the “1-in-10” definition used for this phase of the Restudy also could change.

The Alternatives Evaluation Team (AET) formed a subcommittee to discuss approaches and make a recommendation on how to define a “1 in 10” year LOC performance measure for the purposes of the Restudy. During the development of SFWMD s Upper East Coast Regional Water Supply Plan, a statistical “1 in 10 year drought” year, based on rainfall, was constructed for use using basin models. The SFWMM cannot be used in the same manner, so one of the goals of the subcommittee was to try to decide how to describe an equivalent LOC for the Lake Okeechobee Service Area and the Lower East Coast. Discussions are still occurring on potential ways to run the SFWMM to try to determine if it’s possible to calculate the volume of water that would be needed from the regional system by each basin to meet water supply needs during a “1-in-10 year drought”. The District’s modeling staff does not have time to design and run the SFWMM for this purpose before April 1998. Discussions are also continuing on if or how to describe a “1 in 10 year drought event”. In the interim, the subcommittee agreed to use the frequency and severity of entering into supply-side management events for the agricultural basins in calculating a 1-in-10 year drought LOC. For the Lower East Coast Service Areas, the number of years the lake triggers a water shortage will be used in addition to the number of locally triggered events in calculating a 1-in-10 year drought LOC.

Model Target

To meet all demands (or needs). Recognizing that this may not be feasible, to meet a “1 in 10 year drought” level of certainty; measured by using the frequency of entering into supply-side management operations. An event should not last longer than 7 consecutive months.

Defining the "1-in-10 year drought event" level-of-certainty (LOC) is problematic because of the distribution capability of the regional system, and could be done in any number of ways. Different areas/basins of the District could be in a 1-in-10 year drought event as defined by rainfall at different times, but could receive sufficient water supply via deliveries through the regional system. Assuming that all service areas are experiencing a 1-in-10 year drought at the same time would in fact be an event that would occur less frequently than 1 in 10 years.

Model Output Format

Using the supply-side management reports, count the number of SSM with cutback events that occur. Months with days in SSM without cutbacks are not included. If the total percent cutback for any month is less than 10%, or the number of days with cutbacks is less than 7, the event is not counted. A water year, beginning October and ending September, is used to count events. An event is defined as any year that has a cutback occurrence as described above. For the coastal service areas: use the "simulated annual demands not met due to water restrictions per year" performance indicator, and count the number of events where demands were not met due to Lake Okeechobee. The target would be no more than three events over the simulated period. (Note: Demands not met caused by local well triggers are not considered in the LOSA.)

EAA and LOSA demands – dry years; C43 and C44 Basin Regional irrigation supply and demand not met; Other LOSA supplemental irrigation supply and demands not met; Total irrigation supply and shortages for Seminole Tribe, Big Cypress Reservation; Mean annual EAA/LOSA irrigation demands and demands not met; Report Cumulative total demand, cut-back volume, and cut-back over period of simulation; Lake Okeechobee daily stage hydrograph; Stage hydrographs and depth duration curves for reservoirs

Ecological

Performance Measure
Flows to Lake Worth Lagoon

Date Submitted/Revised
January, 1998

General Planning Objective

This measure addresses several general planning objective identified by the Governor's Commission for a Sustainable South Florida in the Conceptual Plan for the C&SF Project Restudy; provide more natural quality and quantity, timing, and distribution of freshwater flow to estuaries and coral reef ecosystems, and improve and protect habitat quality, heterogeneity, and biodiversity in coastal and associated marine ecosystems

Region
Lake Worth Lagoon, C-51

Restoration Goal

The restoration target is to create estuarine conditions, to the extent possible, in the Lake Worth Lagoon.

Problem Addressed

Lake Worth lagoon historically was a predominately freshwater system that became estuarine periodically through ephemeral inlets opened by hurricanes. The salinity range in the Lake worth Lagoon varies from 0 parts per thousand (ppt) to approximately marine conditions (36 ppt). This is not normally an estuary that becomes hypersaline.

Model Target

An estuarine salinity envelop of 23 ppt to 35 ppt has been chosen as the target salinity range. This is a viable salinity range for a number of organisms many of that are commercially and recreationally important. To attain this salinity a maximum flow needed to be developed. Previous hydrodynamic modeling displayed that 500 cfs creates a steady state salinity of 23 ppt. For the low flow part of the salinity envelop, 0 cfs is the target. Enough groundwater occurs that should still allow estuarine conditions. Based on past modeling, this flow range of 0-500 cfs should create the salinity range of 23 ppt - 35 ppt.

Model Output Format

Mean wet/dry season flows to Lake Worth through S40, S41 & S155 for the 31 year simulation period.
Number of times salinity envelope criteria were not met for the Lake Worth Lagoon (mean monthly flows 1965-1995)

Performance Measure
Continuity: Water Surface Elevations across Barriers

Date Submitted/Revised
January, 1998

General Planning Objective
This performance measure addresses several general planning objectives for the restudy identified by the Governor's Commission for a Sustainable South Florida; improve connectivity and fragmentation of habitats and restore more natural hydropatterns.

Region
Total System

Restoration Goal
Recover spatial and temporal continuity in water depth patterns, across any levees remaining internal to the natural system, consistent with NSM predictions of regional hydropatterns.

Problem Addressed

Canals and levees are widely used to manage the flow of water in south Florida and it is highly unlikely that they will all be removed. Unfortunately, they have several negative effects on wildlife. The deep-water habitat in canals favors larger, predatory fish over smaller, prey species, canals allow exotic fish to reach the Everglades interior easily, and the warmth of the deep water allows these tropical exotics to overwinter farther north than in the past. Both canals and levees physically restrict the movement of smaller species of wildlife, and levees attract terrestrial predators into the marsh interior. More wide-ranging species took advantage of the fluid range of opportunities presented by the wetting and drying cycles in the natural system. Suitable habitat could usually be found somewhere within the system regardless of the season or amount of rain. In the managed system, however, artificial barriers have disrupted these patterns.

Artificial barriers tend to create markedly different water regimes on their upstream and downstream sides. Water usually pools on the upstream side causing the area downstream to become drier. Water quality parameters also may differ widely. Smaller species that do manage to cross a barrier may find inhospitable conditions on the other side. Larger species such as wading birds that feed at particular depths for example, may have to travel much further to feed.

This performance measure addresses the differences in water surface elevations on either side of major artificial barriers in the remaining Everglades.

Model Target

The target condition is water elevation differences across each barrier similar to that predicted by the NSM. Differences of more than one depth class from NSM predictions are considered poor.

Model Output Format

By selecting groups of SFWMM grids on either side of a barrier and comparing the mean water surface elevation classes of the two groups, an indicator of continuity of landscape can be derived. Groups of cells were used to avoid the pitfalls inherent in single cell comparisons. Many of the barriers in the SFWMM are artificially located on the boundary between cells. In those cases, adjacent cells on either side were used. In other cases, cells containing barriers were excluded to avoid the anomalous elevation values resulting from the influence of the barrier. Adjacent cells were selected so they would have similar soils, vegetation and hydrology. Of course, cells across boundaries may naturally differ in soil, vegetation and hydrology. This measure seeks to evaluate not whether differences exist, which they undoubtedly do, but whether those differences are consistent with NSM predictions.

Comparisons are made to sets of cells on either side of the following barriers: Tamiami Trail (east), Tamiami Trail (west), L-67, and L-28, Alligator Alley, the levee/canal between WCA-2 and WCA3 and the divide between WCA1 and WCA-2A. Cells within the groups are pooled on either side of the barrier by determining the time series of mean weekly water elevations for each set of cells. The difference between these values for the two groups is then compared to the difference between the same groups of cells predicted by the NSM. Water surface elevations are used instead of depth estimates because depth estimates inherently have more error than water elevations, especially across levees where there may have been differential soil loss or accretion and where the collection of topographic data may not be similarly accurate on either side. Comparing water surface elevations instead eliminates this source of error. Additionally, the model is calibrated to water surface elevations and not to depths.

The Performance Measure is a list of mean weekly water surface elevations, upstream minus downstream for each barrier for each alternative next to those predicted by the NSM and a histogram showing the total number of weeks in which the upstream-downstream water elevation differences were: 1) within 0.0 to 0.249 feet of NSM, 2) greater than 0.25-0.49 feet different, 3) less than 0.25-0.49 feet different, etc. using whatever increment best illustrates the range of data for the model runs.

Selected cells are listed below. Superscript G = gauge, IR*n* = Indicator Region Cell

Divide between Loxahatchee NWR (WCA-1) and WCA-2A.

Performance Measure
Fragmentation: Miles of Canals and Levees Affecting Natural Areas

Date Submitted/Revised
February, 1998

General Planning Objective

This performance measure addresses several general planning objectives for the restudy identified by the Governor's Commission for a Sustainable South Florida; improve connectivity and fragmentation of habitats and restore more natural hydropatterns.

Region
Total System

Restoration Goal

Fill in artificial water features, remove barriers or otherwise make these structures biologically invisible to the surrounding landscape.

Problem Addressed

In its effort to control floodwaters and provide water supply, the C&SF Project created miles of canals, levees, and water control structures with associated deep pools. Canals and levees usually coexist; construction of a canal usually means a spoil levee exists alongside it just as a levee requires a borrow canal. Roadway construction usually involves combinations of levees and canals, sometimes with culverts to allow water to flow underneath. Water control structures are usually even more complex, involving combinations of levees, canals and deep pools. In some places, multiple canals, levees and water control structure form intricate patterns - and formidable barriers to wildlife.

When levees block the flow of water, they also restrict the movement of aquatic and semi-aquatic life forms in the water. Land-based predators use the levees to invade the marsh interior, preying upon animals that try to cross the intrusive fingers of terrestrial habitat. Levees also act as conduits, allowing terrestrial plants to invade. Canals act as corridors particularly for non-native animals and plants that can extend their ranges rapidly from points of introduction and can move into wetlands where they can alter habitats and affect food webs (Loftus and Kushlan 1987; Loftus 1986). Artificial, deep-water habitats provide thermal and spatial refuge to large numbers of both non-native and native aquatic predators in the dry season, enhancing their survival and ultimate population sizes. During the dry season, these predators prey heavily on small marsh fishes and invertebrates moving in from the adjacent wetlands (Howard et al. 1995). Alternatives that accomplish their purpose without adding to the present array of levees, canals, culvert pools, and borrow ponds in the system are considered to do no further harm but do not “restore” connectivity. Alternatives that fill in artificial water features, remove barriers or otherwise make these structures biologically invisible to the surrounding landscape are considered a positive step towards restoration. Alternatives that require a net addition of structures are detrimental.

Model Target

Minimize the extent of canals and levees internal to the remaining natural system.

Model Output Format

Outputis a table showing the number of miles of canals and, levees bordering or bisecting natural areas for each alternative.

Performance Measure
Sheetflow: Volumes Across Transects in the WCAs and Everglades National Park

Date Submitted/Revised
February, 1998

General Planning Objective

This performance measure addresses several general planning objectives for the restudy identified by the Governor's Commission for a Sustainable South Florida; restore more natural hydropatterns, including associated sheetflow, and improve connectivity and reduce fragmentation of habitats.

Region
Total System

Restoration Goal

Restoring the appropriate volume and direction of sheet flow to large areas of the freshwater marshes will allow the system to once again naturally shape tree islands, take up nutrients, precipitate phosphorus and calcium carbonate into the substrate, and retain water into the dry season. Restoring volumes of flow to Shark River Slough (the largest drainage in the system) and across the marl prairies of southern Everglades and through the system of creeks ringing Florida Bay will increase freshwater inputs into the Bay. Restoring freshwater flows into the Bay, particularly during the dry season, is badly needed to recreate the proper salinity patterns and circulation needed to restore the ecology of the system.

Problem Addressed

Sheet flow is one of the defining characteristics of the pre-drainage Everglades. Water once continuously flowed from the shore of Lake Okeechobee through the Everglades to Shark River Slough and on into Florida Bay. In the managed system, the Lake and the Water Conservation Areas have been impounded. Flow patterns out of Lake Okeechobee have shifted from primarily wet season flows in response to rainfall to dry season flows in response to urban and agricultural water supply demands.

While depths may be similar to the pre-drainage system, the River of Grass is now stagnated. The Water Conservation Areas, divided by levees and canals, are now a series of pools where water travels with less velocity and in different directions of flow. "Ponded systems favor certain species and flowing systems favor others. There are many physicochemical differences in the two systems: food types and sources, migration of macroinvertibrates, dispersion of nutrients, aeration and diffusion of gases in water, particulate suspension, and thermal stratification are some examples. Ponding in the WCAs amounts to regulation for certain species—the zoo approach that is not an ecosystem approach. From a water conservation perspective, ponding may be wise; and in a water-limited system, ponded water for fish is a real improvement over no water for fish. Is would be possible to match regulated hydroperiods month to month with natural hydroperiods and still have a completely different ecosystem due to the difference in water movement. This is another reason why a hydroperiod analysis is singularly insufficient to create the intended biological conditions." (U. S. Corps of Engineers, 1994).

System-wide, there has also been a loss of dry season lag flows from the dense sawgrass plain that formerly covered the present Everglades Agricultural Area. "Impoundment of water in the Water Conservation Areas and diversion of surface water flows to the east, combined with groundwater and levee seepage loses eastward in the modified system, have significantly contributed to reduced flows and the resultant loss of persistent hydroperiods in the southern Everglades flows and the resultant loss of persistent hydroperiods in the southern Everglades." (Davis and Ogden 1994).

The overall flow pattern has changed, too, now that the deepest part of the system, east of the Dade-Broward levee, has become an urban landscape. More water is forced through the remaining area, creating excessive depths in the impounded areas. In Florida Bay, decreased freshwater flow and increased salinity have contributed to the deterioration of estuarine productivity in Florida Bay. Pink shrimp, snook, redfish and recruitment have been reduced. Reproductive success of ospreys, great white herons, and many wading birds that nested in the estuarine ecotonal areas have been lowered. Wading bird colonies have collapsed as once-persistent pools in lower Shark River Slough have dried. Mortality in seagrass beds and mangroves has also been linked to reduced freshwater flows.

Model Target

Flow volumes across selected groups of transects predicted by NSM version 4.5 Final.

Model Output Format

A relative value for improvement in sheetflow in the Everglades marshes was obtained by comparing flow volumes across a number of transects in the north, central and southern Everglades and Big Cypress with those predicted by the NSM version 4.5 Final. Twenty-six transects were chosen throughout the Water Conservation Areas, Big Cypress, and Everglades National Park. The average annual volumes of flow for the wet season and dry season for each alternative were compared to the wet season and dry season volumes from NSM version 4.5 Final. Dry season volumes were considered more important. The 26 transects were grouped into five categories representing their general area: Big Cypress Group

(T24, T25, T26), Central Everglades (WCA-3A) Group (T7, T8, T12), Southern Everglades Group (T21, T23A, B, &C), Tamiami Trail Group (T17, T18) and the L-67 Group (T13, T14). Then for each group, an index was calculated for each transect based on the wet season and dry season average annual overland flows. For each base condition and plan, the flow value was divided by the NSM value to obtain wet season and dry season proportions, which were then scaled. Scaling, using the same curve formula described above was used to obtain values between 0.0 and 1.0. In cases where the proportion of wet season flows exceeded NSM, they received a value of 1.0. For dry season flows, excess flows were treated the same as insufficient flows.

Performance Measure
Maintenance of desirable salinity conditions within the St. Lucie Estuary
# of months with mean monthly flow < 300 cfs
# of months with mean monthly flows > 2,800 cfs
# of months with mean monthly flows were > 4,500 cfs
# of months with mean monthly flows > 2,800 cfs (local basin runoff)
additional # of months with mean monthly flows > 2,800 cfs (Lake Okeechobee regulatory releases)

Date Submitted/Revised
June, 1998

General Planning Objective

This performance measure suite is linked to the St. Lucie and Caloosahatchee conceptual model (Grey and Haunert). It addresses several general planning objective identified by the Governor's Commission for a Sustainable South Florida in the Conceptual Plan for the C&SF Project Restudy; provide more natural quality and quantity, timing, and distribution of freshwater flow to estuaries and coral reef ecosystems, and improve and protect habitat quality, heterogeneity, and biodiversity in coastal and associated marine ecosystems

Region
Caloosahatchee Estuary

Restoration Goal

Reduce high volume and minimum discharge events to the estuary to improve estuarine water quality and protect and enhance estuarine habitat and biota.

Problem Addressed

The Caloosahatchee Estuary is located on the southwest coast of Florida, and discharges into Charlotte harbor, and then into the Gulf of Mexico. The Caloosahatchee is also connected to Lake Okeechobee through the C-43 canal (Caloosahatchee River), and there are a series of smaller drainage works in association with substantial agriculture development in the watershed. The construction of a water control structure (Franklin Lock and Dam) downstream of Lake Okeechobee has decreased the tidally influenced portion of the estuary, allowing for a convenient use of the C-43 as a potable water supply.

To determine appropriate water quantity inflows to the estuary, biological indicators with definable salinity preferences were chosen. A favorable range of salinities for the estuary were determined (referred to as the salinity envelope) based on the requirements of SAV (*Vallisneria*). The favorable ranges of salinity (salinity envelope) have been related to volumes of freshwater flow to the estuary and a target range of flows was determined. In order to meet the salinity envelope criteria the surface water flows coming from the watershed as well as from ground water should be in the range of 300cfs - 2800cfs.

Model Target

The performance measures have targets based on flow that would support optimum hydrologic conditions conducive of optimum quality habitat for fish, wildlife, and other aquatic resources. The targets are based on optimization model outputs, natural variation that would occur during the period 1965-1995, and desirable salinity conditions for existing and potential aquatic resources within the Caloosahatchee Estuary.

# of months with mean monthly flow < 300 cfs : Target minimum mean monthly flows to the estuary are 300 cfs to protect *Vallisneria*, tape grass and support juvenile fish populations. This flow could come from the watershed (including groundwater), Lake Okeechobee (via S-79), or a combination of the two. The results of hydrologic modeling indicate that the optimum scenario would have no more than 60 months of mean monthly flows of <300 cfs. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

b. High Discharge Criteria, # of months with total mean monthly flows > 2,800 cfs : The results of hydrologic modeling indicate that the optimum scenario would have no more than 22 months of mean monthly flows of >2,800 cfs. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

High Discharge Criteria, # of months with total mean monthly flows were > 4,500 cfs : The results of hydrologic modeling indicate that the optimum scenario would have no more than 6 months of mean monthly flows of >4,500 cfs. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

# of months with mean monthly flows > 2,800 cfs (C-43 basin runoff) : The results of hydrologic modeling indicate that the optimum scenario would have no more than 22 months of mean monthly flows of >2,800 cfs. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

additional # of months with mean monthly flows > 2,800 cfs (Lake Okeechobee regulatory releases, Zone A discharges) : The results of hydrologic modeling indicate that the optimum scenario would have no additional months of mean monthly flows of >2,800 cfs (from Lake Okeechobee). The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

Model Output Format

# of months with mean monthly flow < 350 cfs
# of times the 14-day moving average flow is > 2800 cfs (local basin runoff)
additional # of times the 14-day moving average flow is > 2800 cfs (Lake Okeechobee releases)

High Discharge Criteria, # of times mean monthly flow is > 2800 cfs
High Discharge Criteria, # of times mean monthly flow is > 4500 cfs

Performance Measure
Maintenance of desirable salinity conditions within the St. Lucie Estuary
# of months with mean monthly flow < 350 cfs
# of months with mean monthly flows > 1,600 cfs
# of months with mean monthly flows were > 2,500 cfs
# of times the 14-day moving average flow is > 1600 cfs (local basin runoff)
additional # of times the 14-day moving average flow is > 1600 cfs (Lake Okeechobee regulatory releases)

Date Submitted/Revised
January, 1998

General Planning Objective

This performance measure suite is linked to the St. Lucie and Caloosahatchee conceptual model (Grey and Haunert). It addresses several general planning objective identified by the Governor's Commission for a Sustainable South Florida in the Conceptual Plan for the C&SF Project Restudy; provide more natural quality and quantity, timing, and distribution of freshwater flow to estuaries and coral reef ecosystems, and improve and protect habitat quality, heterogeneity, and biodiversity in coastal and associated marine ecosystems

Region
St. Lucie Estuary

Restoration Goal

Reduce high volume discharge events to the estuary to improve estuarine water quality and protect and enhance estuarine habitat and biota.

Problem Addressed

The St. Lucie Estuary is located on the southeast coast of Florida, and discharges into the Indian River Lagoon and Atlantic Ocean at the St. Lucie Inlet. The estuary encompasses about eight square miles, and the historic watershed was estimated to be about 1/3 the size of its present configuration. Due to extensive agricultural and urban drainage projects beginning in the 1910s, the present day watershed area has been expanded to almost 775 square miles. Major canals in the watershed include the C-23 and C-24 canals, part of the Central and South Florida Flood Control Project. In addition, the estuary is linked to Lake Okeechobee by the

C-44 canal that is utilized for both navigation and the release of floodwaters from Lake Okeechobee.

To determine appropriate water quantity inflows to the estuary, biological indicators with definable salinity preferences were chosen. A favorable range of salinities for the estuary were determined (referred to as the salinity envelope) based on the requirements of SAV and oysters. Woodward-Clyde, in a literature review report developed for the District in 1998, summarizes the approximate salinity tolerances for selected SAV and American oyster. A report on the abundance and type of SAV species by Phillips and Ingle (1960), provided the most complete source of information on SAV occurrence and abundance in the St. Lucie Estuary. This survey of SAV which was conducted from September 1957 to March 1959 revealed that the three most commonly found species of SAV in the estuary at the time were shoal grass (outer and middle estuary), manatee grass (outer estuary), and widgeon grass (north fork). They also reported on the salinity tolerance, normal, common and optimum range for all species. The normal tolerance range for shoal grass is 5-55 ppt; for manatee grass, 17-44 ppt; and for widgeon grass, 0-45 ppt. These numbers were based on reviewed literature, and all species can withstand even greater salinity fluctuations for short periods of time. The salinity tolerance ranges were also summarized for the different life cycle stages of the American oyster. The optimum range for adults and juveniles is 10-20 ppt, 20-23 for spat, 23-27 for larvae and embryos and 15-20 ppt for a sustainable population (Woodward-Clyde 1998). These favorable ranges of salinity (salinity envelope) have been related to volumes of freshwater flow to the estuary and a target range of flows was determined. In order to meet the salinity envelope criteria the surface water flows coming from the watershed as well as from ground water should be in the range of 350cfs - 1600cfs

Model Target

The performance measures have targets based on flow that would support optimum hydrologic conditions conducive of optimum quality habitat for fish, wildlife, and other aquatic resources. The targets are based on optimization model outputs, natural variation that would occur during the period 1965-1995, and desirable salinity conditions for existing and potential aquatic resources within the St. Lucie Estuary. The target salinity gradients in St. Lucie Estuary were determined by a hydrodynamic salinity model (Morris 1987) combined with estimates of salinity requirements for two indicator species in the estuary, *Halodule wrightii* (shoal grass) *and Crassostrea virginica* (American oyster).

# of months with mean monthly flow < 350 cfs : Target minimum mean monthly flows to the estuary are 350 cfs to protect oysters near the Roosevelt Bridge, promote brackish aquatic plant growth, and support juvenile fish populations. This flow could come from the watershed (including groundwater), Lake Okeechobee (via S-80), or a combination of the two. The results of hydrologic

modeling indicate that the optimum scenario would have no more than 50 months of mean monthly flows of <350 cfs. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

# of times the 14-day moving average flow is > 1600 cfs (local basin runoff) : Historically, the high flow events have been the most destructive. The results of hydrologic modeling indicate that the optimum scenario would have no more than 13 events of 14-day moving average flows of >1600 cfs. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

# of times the 14-day moving average flow is > 1600 cfs (Lake Okeechobee releases) : The results of hydrologic modeling indicate that the optimum scenario would have no months of 14-day moving average flows >1600 cfs from Lake Okeechobee releases. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

# of times mean monthly flow is > 1600 cfs : The results of hydrologic modeling indicate that the optimum target would have no more than 9 months of mean monthly flows of >1600 cfs. This target dictates a maximum flow that will provide suitable habitat for important benthic communities. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

# of times mean monthly flow is > 2500 cfs : The results of hydrologic modeling indicate that the preferred scenario would have no more than 3 months of mean monthly flows of >2500 cfs. Mean monthly flows above 2500 cfs result in freshwater conditions throughout the estuary causing severe impacts to estuarine communities. The estuary data for the alternatives is taken from the performance measures bar graphs and tables.

Model Output Format

# of months with mean monthly flow < 350 cfs
# of times the 14-day moving average flow is > 1600 cfs (local basin runoff)
additional # of times the 14-day moving average flow is > 1600 cfs (Lake Okeechobee releases)
# of times mean monthly flow is > 1600 cfs
# of times mean monthly flow is > 2500 cfs

Performance Measure
Canal Discharges to Biscayne Bay

Date Submitted/Revised
May, 1998

General Planning Objective

This performance measure addresses several planning objectives identified by the Governor's Commission for a Sustainable South Florida in the Conceptual Plan for the C&SF Project Restudy; Improve habitat quality and heterogeneity, Provide more natural quality and quantity, timing and distribution of freshwater flow to estuaries, and improve and protect habitat quality, heterogeneity, and biodiversity in coastal and associated marine ecosystems.

Region

For this performance measure, Biscayne Bay is considered to be bounded by Snake Creek to the north (Oleta River State Park) and the southern border of Biscayne National Park to the south.

Based on historical accounts and scientific studies, Biscayne Bay has been classed as a positive, shallow, tidal, bar-built estuary (Kohout and Kolipinski 1967). The term positive refers to the condition of salinity being less than seawater (Hela et al. 1957). The salinity gradient that established estuarine habitat in Biscayne Bay is dependent on both surface and ground water flows (Fatt and Wang 1987). The effect of regional drainage projects on these flows has been to disrupt salinity patterns and impair coastal ecosystem function by altering the timing and amounts of freshwater input to the bay.

Restoration Goal

Reduce excessive canal discharges to the bay, provide a stable brackish water habitat during the wet season, and provide more water during dry periods to prevent hypersaline conditions from impacting important marginal wetlands and nearshore habitats.

Problem Addressed

Based on historical accounts and scientific studies, Biscayne Bay has been classed as a positive, shallow, tidal, bar-built estuary (Kohout and Kolipinski 1967). The term positive refers to the condition of salinity being less than seawater (Hela et al. 1957). The salinity gradient that established estuarine habitat in Biscayne Bay is dependent on both surface and ground water flows (Fatt and Wang 1987). The effect of regional drainage projects on these flows has been to disrupt salinity patterns and impair coastal ecosystem function by altering the timing and amounts of freshwater input to the bay.

While accomplishing the goal of flood control, the presence and operation of the canals has had profound hydrological and ecological consequences on Biscayne Bay (Teas et al. 1976, Thorhaug et al. 1976, Hoffmeister 1974). The temporal and spatial pattern of freshwater inflow to the bay was fundamentally altered to one of point source discharges (canal mouths) that are characterized by abrupt periods of high discharge and minimal or no discharge to the bay. Although the general pattern of wet and dry seasons still persist, operation of coastal water control structures results in rapid changes in local salinity gradients that may occur on a daily basis and over several months, particularly during the rainy season (Fatt 1986). During the dry season, hypersalinity has been observed as a result of evaporation, retention of canal flow, and bay circulation (Lee 1975). While abrupt changes in salinity can occur naturally in nearshore habitats, they usually result from infrequent events such as hurricanes and tropical storms. The effects of salinity changes have been documented for fish (e.g. Davenport & Vahl 1975, Provencher et al. 1993, Serafy et al. in press) and for invertebrates (e.g. Brook 1982, Montegue and Ley 1993, Irlandi et al. in press). The presence and operation of the canals and construction of permanent oceanic inlets has resulted in a loss of estuarine function and shifted Biscayne Bay to more of a lagoon, adversely impacted from freshwater pulses and highly variable salinities. These conditions have been at least partly responsible for the loss of historically abundant estuarine species, such as red drum, black drum, and eastern oyster, the loss of juvenile fish habitat, and the significant increase in stress-tolerant fish species such as the gulf toadfish (Serafy et al., in press).

Model Target

Model results were compared to surface water budget targets that were considered appropriate to achieving restoration of the Biscayne Bay ecosystem. These targets consist primarily of the existing average annual inflow to Biscayne Bay as defined by the 1995 Base hydrologic period, with a 2% increase in total inflow budget to be applied in the dry season to the Central and South Bay regions.

A separate target for Snake Creek (S29) was also developed based on canal discharge that would maintain salinities for oyster survival. average salinity (measured at one meter depth) near the mouth has averaged less than 20 ppt. since 1988. Viable oyster communities appear to thrive in the area forming the headwaters of the Oleta River. By use of linear regression modeling, a total monthly volume of 13,300 acre-feet equates to 20 ppt. salinity concentration. This should be viewed as a minimum monthly flow. Excessive flow does not seem to be problem in general.

Model Output Format

Based on SFWMM hydrologic model output, the bay was divided into five regions from north to south, based on the mean monthly discharge from water control structures in these regions. The regions were Snake Creek (S29), North Bay (G58, S28, S27), Miami River (S25, S25B, S26), Central Bay (G97, S22, S123), and South Bay (S21, S21A, S20F, S20G). Model output for each alternative provides results as the sum of discharge from the structures in each region in terms of a mean annual wet season and dry season volume.

D-C.1 INTRODUCTION

README File for Across Trophic Level System Simulation (ATLSS) Model Outputs for the Central and Southern Florida Comprehensive Study Review (Restudy) FTP Site (Address: ftp://ftp.tiem.utk.edu/pub/atlss/)

Prepared by The Institute for Environmental Modeling
University of Tennessee, Knoxville
Knoxville, TN 37996-1610

With Financial Support from The University of Tennessee, the U.S. Geological Survey (through Cooperative Agreement #1445-CA09-95-0094), and the U.S. Army Corps of Engineers, and a partial Software grant from O2 Technology Incorporated.

A complete description of the ATLSS modeling and the results can be accessed at either the U.S. Army Corps of Enginers, Jacksonville District, ATLSS home page (http//www.restudy.org/atlss/) or as appendix D of the CD version of this report. The following sections presents a description of the individual models used in the ATLSS assessment for each alternative scenario and the results of the scenario. Except for examples this report does not contain output files referred to in the write ups. The out put files are avalibe at http//www.restudy.org/atlss/ or as appendix D of the CD version of this report. A detailed description of the hydrologic components for each modeled alternative can be found in Section 9 of the Feasibility Report/PEIS.

These materials may be used by all U.S. and State government agencies and non-profit organizations to aid evaluation of the Central and Southern Florida Comprehensive Study Review (hereafter the RESTUDY). Use for any other purpose, including all commercial use involving monetary payment for the materials, is prohibited without express written consent of the copyright holders.

TIEM/UTK shall not be held liable for improper or incorrect use of the data, information, or materials described and/or contained herein. All materials included are not legal documents and are not intended to be used as such. The materials here included may change over time without notice, and the information contained may be inaccurate or unreliable if used for purposes other than those for which it was constructed. All information contained herein is provided "as is" without warranty of any kind, and the entire risk as to the results and performance of any information obtained from this Report is entirely assumed by the recipient.

The results included on the ATLSS website (http://www.restudy.org/atlss/index/html) have been obtained with the assistance of a financial support from a variety of organizations. The statements, findings, conclusions, recommendations, and other data located on this Site are solely those of the authors and do not necessarily reflect the views of The University of Tennessee, the U.S. Geological Survey, the US Army Corps of Engineers, O2 Technology Incorporated, or any other organization providing support for the work included.

D-C.1.2 ATLSS Objectives

The Everglades and Big Cypress Swamp of South Florida are characterized by complex patterns of spatial heterogeneity and temporal variability, with water flow being the major factor controlling the trophic dynamics of the system. A key objective of modeling studies for these systems is to compare the future effects of alternative hydrologic scenarios on the biotic components of the systems. Due to the varying scales at which trophic interactions occur, and the importance of population structure and individual behavior for population prediction in higher trophic level organisms, use of a single modeling approach is not appropriate.

A large group of collaborators has been developing a set of models (the linked collection of these is called a multimodel) designed to integrate several approaches for different trophic levels of the system including: (1) process models for lower trophic levels (including benthic insects, periphyton and zooplankton), (2) structured population models for functional groups of fish, macroinvertebrates, amphibians and reptiles and (3) individual-based models for consumers (including Cape Sable Seaside Sparrow, Snail Kite, wood storks, white-tailed deer, and Florida panther). The models (together called ATLSS for Across Trophic Level System Simulation) are still evolving. The current collection of models being applied to the Restudy with outputs included on this Site have all been produced at TIEM/UTK, and will be added to as additional model components are completed. ATLSS is integrated across the freshwater landscape of South Florida, coupled to a variety of GIS maps, and involves spatial scales of resolution as small as 28 m. ATLSS makes use of input hydrology data obtained at a 2 mile by 2 mile resolution, links this with a model for fine-resolution topographic differences called the pseudotopography, and produces from this estimates of hydrology at 500 m or finer resolution. This fine-resolution hydrology is then utilized throughout the collection of ATLSS components.

The overall ATLSS project is coordinated by Dr. Donald DeAngelis of the Biological Resources Division of the U.S. Geological Survey.

D-C.1.3 Subdivisions of S. Florida for Analysis of ATLSS Model Output

The large size of the area being evaluated for the Central and South Florida Project Restudy requires that it be broken down into subregions for assessing the impacts of alternative hydrologic restoration plans. Some of the subregions, such as the Water Conservation Areas, are clearly delineated by physical boundaries such as canals and levees. Other subdivisions, such as resource management units within Everglades National Park and Big Cypress National Preserve, may have no physical features associated with them. In order to meet the information needs of the many professional disciplines involved in the restudy, the ATLSS Project has developed a set of subdivisions of the region that include both physical and administrative boundaries.

The physically bounded subregions used by ATLSS are defined to correspond to the internal structure of the South Florida Water Management Model (SFWMM), which is being used to generate the hydrological predictions for the various restoration alternatives. These regions are EAA, WCA-1, WCA-2A, WCA-2B, WCA-3A, and WCA-3B. Another subregion, ENP-East, is further divided into smaller subregions for natural resource management reasons. Each of these regions corresponds to hydrologic basins that are defined within the structure of the SFWMM. Because the SFWMM is based on a rectilinear grid of connected cells, each of which is 2 miles x 2 miles in size, these basins are defined within the SFWMM as groups of 2 x 2 mile squares. Thus, although in reality these basins are physically defined by a continuous series of canals and levees, in the model their boundaries are represented as "steps" that are 2 miles on a side. As a result, the boundaries of these areas do not correspond directly to the linear features on the landscape. For example, around the boundaries of the Water Conservation Areas, the perimeter canals and levees may either be inside or outside the boundaries of the WCAs as they are represented in the SFWMM. These approximations result in portions of the landscape being modeled with water that does not correspond to that actually experience by that area (e.g., the "downstream" side of a levee being modeled with water appropriate to the "upstream" side of the levee). To address these boundary discrepancies, ATLSS model output is "trimmed" to exclude the areas where these discrepancies occur. This assures that the potentially distinct hydrologic dynamics of one basin are not inadvertently included in the output for another basin.

One basin boundary illustrates this issue particularly clearly. On the actual landscape, the southern boundary of the WCA-3A basin corresponds to the northern boundary of the Everglades National Park-East basin, which is the Tamiami Trail levee and canal. However, because of the 2 x 2 mile grid structure of the SFWMM, the actual boundary (the Tamiami Trail) runs through the center of the 2 x 2 mile cell that lies south of the model's internal boundary for the two basins. As a result, the one mile wide strip that lies to the north of the Tamiami Trail, which in reality is in WCA-3A and 3B, is modeled by the SFWMM as if its hydrologic conditions were identical to the area south of the trail, in Everglades National Park. For this reason, the ATLSS subdivisions bordering this area are defined to exclude this 1-mile-wide strip where the water does not correspond to the actual location. Thus, the northern boundary of the Everglades National Park is set at the Tamiami Trail, while the southern boundary of WCA-3 is set 1 mile to the north, at a position that corresponds to the internal boundary of the SFWMM. To some degree, this same boundary discrepancy occurs at all the internal boundaries of the SFWMM. All subdivisions for ATLSS model output are defined to exclude areas where water is modeled inappropriately because of a mismatch between the positions of internal SFWMM basin boundaries and the actual physical boundaries on the landscape. Exclusion of these boundary areas results in the area described in ATLSS model output being slightly smaller than the actual physical size of certain subregions, particularly the Water Conservation Areas.

Away from the boundaries of the SFWMM boundaries, either inside the basins, or outside them (i.e., Big Cypress National Preserve), boundaries for ATLSS output subdivisions are defined to correspond to either actual physical features (e.g., roads where appropriate) or to administrative boundaries.

D-C.1.4 Listing of ATLSS Models Applied to Restudy

The ATLSS modeling system includes a wide range of model types, ranging from relatively simple physically-based deterministic models, such as the high resolution landscape hydrology model that processes the output of the South Florida Water Management Model (SFWMM) to produce the hydrology for ATLSS, to the individual-based models of the highest trophic levels, which include animal energetics, behavior, and movement. Because the ATLSS modeling system is based on the premise that higher trophic levels (such as wading birds and panthers) are strongly influenced by the food resources on which they depend, ATLSS model output can be summarized at any level in the trophic system, from the physical conditions that influence plants and animals, through the growth of plants and algae, to the population dynamics of herbivores and the predators that eat them.

The different types of models can be characterized in terms of their temporal and spatial complexity and the detail with which they represent biological and ecological processes. Different levels of model output can serve different objectives within the framework of the Central and South Florida Restudy. The basic components of ATLSS being utilized in the initial phases of the Restudy are below:

Pseudotopography

High Resolution Hydrology

Hydroperiods Associated with Vegetation Types

Cape Sable Seaside Sparrow Breeding Potential Index

Wading Bird Foraging Condition Index

White-tailed Deer Breeding Potential Index

Landscape Fish Model

Cape Sable Seaside Sparrow Individual Based Model

Snail Kite Breeding Potential Index

D-C.1.5 Output Formats for ATLSS Models

D-C.1.5.1 Maps

All standard maps cover the entire region of the SFWMM, with high resolution data summarized into 500 x 500 meter cells (each of which could represent as many as 300 high resolution pixels). These maps are produced using either time-averaged data (e.g., means, sums) for specified time intervals, or correspond to specific time points during the 31-year simulation period. All maps are produced for a Set of comparisons with 3 maps on an 8.5 x 11 inch page. The right map is for the new alternative scenario, the left map is for the base case (e.g., the Future without project condition), and the middle map shows the differences between the scenario and the base case (i.e., the scenario data minus the base case data). Most comparison maps are accompanied by tables with quantitative analysis of the data summarized by the above described spatial subdivisions.

D-C.1.5.2 Data Tables

Quantitative analyses of changes in the spatial distribution of properties such as hydroperiod, maximum water depth, as well as the surface area with a particular hydroperiod or vegetation type, are presented as data tables summarized by the above described spatial subdivisions. For each analysis of interest (e.g., average hydroperiod for each vegetation type during the 5 wettest years) there is a separate table entry for each subdivision. In addition to the values for each scenario being compared (e.g., total area in a given hydroperiod range) the table also presents the absolute difference between the scenarios, as well as the percentage change attributable to the alternative being evaluated.

D-C.1.5.3 Time-series Graphs

Population size estimates that are produced by ATLSS models are presented as graphs that show the projected changes in population size over the 31-year time period. These graphs show the population projections for an alternative scenario and the base case, plus the difference between the two. Multiple graphs are included on a single page, with each graph corresponding to the population dynamics in one of the drainage basin/management units (or other subunits appropriate to the species being considered). Particular models include specialized forms of this, such as the time series of size histograms for the fish model.

D-C.1.6 Sources of Uncertainty for ATLSS Models

All model outputs contain uncertainty or variability (defined as deviations from actual or expected values of predicted parameters) that results from a number of different sources. While this uncertainty should be considered when evaluating model output for assessment and policy decisions, it is also true that the actual uncertainty of model predictions is extremely difficult to quantify without a very large effort in statistical evaluation and "error analysis." Understanding the different sources of this uncertainty helps clarify the appropriate use of model output. There are four primary sources of uncertainty that must be considered in assessing the potential impacts of wetland restoration activities in South Florida:

1) Uncertainty resulting from lack of knowledge about future climate and weather. The planned use of the 1965-1995 historical climate as the basis for scenario evaluation means that model output cannot be considered a prediction of the future hydrologic conditions or the future condition of plant and animal populations. Scenario evaluations compare the relative performance of different hydrologic management plans under the same climatic conditions, but cannot be considered to be a prediction of the ecological conditions that will occur after the restoration measures are implemented. Any changes in climate or climatic variability, including increased hurricane frequency or intensity, may result in major differences between model projections based on 1965-1995 climate and the conditions that actually occur in the future.

2) Uncertainty resulting from imperfect understanding and representation of major processes in physical and biological models. This source of uncertainty can be reduced by research that leads to better representation of physical and biological

processes in models, which can also help to identify the most important parameters and the spatial and temporal scales at which they should be measured and modeled.

3) Uncertainty resulting from imprecise measurements of important physical and biological parameters used in equations that describe processes or initial conditions. This source of uncertainty can be quantified using methods known as "sensitivity analysis" and can be reduced by improved parameter estimates based on more accurate measurements in the field, better representation of physical and biological processes, and use of appropriate temporal and spatial resolutions for measuring and modeling physical and biological processes.

4) Uncertainty resulting from randomness in models with stochastic components (such as the probability of a predator encountering its prey during a particular time interval). This source of uncertainty can be reduced by increasing the number of "replicate" computer simulations, among which the only differences will be those that result from random processes included in the models. An increased number of replicates will result in more accurate "confidence intervals" and means.

For complex models such as those included as components of ATLSS, issues of model validation and error propagation are difficult to address. The basis of ATLSS use for this Restudy is that what we wish to produce are relative assessments of different scenarios, rather than exact quantitative predictions for any particular scenario. Under the assumption that the uncertainties mentioned above do not interact differentially with changes in scenarios (a reasonable assumption for scenarios produced by methods external to the models being used to assess them, in this case ATLSS), it is reasonable to hypothesize that errors propagate similarly in model runs on different scenarios. This is a hypothesis however that would require considerable additional testing to evaluate.

D-C.1.7 File Formats and Performance Set File Naming Conventions

ATLSS FTP Performance Set File Naming Conventions

File Name:

```
XX XX XXXX . XXX
-- -- ---- ---
|  |  |  |
|  |  |  |=> File Type
|  |  |
|  |  |=> Content Descriptor
|  |
|  |=> Model Code
```

|
|=> Input(s) Identifier

Input(s) Identifier:

1st Character = E -> Base with Existing Project Conditions (C1995-Base) F -> Base without Existing Project Conditions (F2050-Base)
2cnd Character = [0-9, A->Z] -> Scenario or Base Identifier _ (underbar) -> No Scenario, a run of a Base Condition only
Examples: F_ = File is associated with a run of the F2050 base with only. No comparison with another scenario are represented.
F0 = File is associated with a run of the first scenario received. File will contain a comparison of the first scenario (alt0) and the F2050 base.

Model Code: Code for the model that generated the output characterized by the file.

Examples:

HY = Hydrology
VG = Vegetation
BC = Cape Sable Seaside Sparrow Breeding Potential Index
BD = White-tailed deer Breeding Potential Index
FC = Wading bird Foraging Condition Index
FI = Fish
SP = Sparrow
DR = Deer
PN = Panther

Content Descriptor:

Set by the modeler to describe the contents of the file.

Examples:

69 = Performance set represents the year 1969
CR = Model was executed at a Coarse (2 mile) Resolution
FR = Model was executed at a Fine (500 meter) Resolution

File Type:

Indicates the format of the file and the type of contents.

Examples:

PDF = ADOBE's PDF (maps, time series charts).
TXT = Plain ASCII text file (tables, listings).
DOC = Metadata file describing the contents of the file(s) indicated by the base file name.

IX. Listing of ATLSS Model Files Included on FTP Site

Directory ftp://ftp.tiem.utk.edu/pub/atlss

README - High level ATLSS description and discussion of files and their naming conventions (this file).

00Index.DOC - Description and transaction log of files in the ATLSS ftp directory

CSSSBPI_.DOC - Description of the Cape Sable Seaside Sparrow Breeding Potential Index Model and it's performance set output files.

FISHREUN.PDF - Map showing the reporting units or areas used in the performance set output files for the Landscape Fish Model.

FISH____.DOC - Description of the Landscape Fish Model and it's performance set output files.

HYDRO___.DOC - Description of the High Resolution Hydrology Model and it's performance set output files.

SPARROW_.DOC - Description of the SIMSPAR Individual-based Cape Sable Seaside Sparrow Model and it's performance set output files.

REPUNITS.PDF - Map showing the reporting units or areas used in the performance set output files for all models except the Landscape Fish Model.

WBBPI___.DOC - Description of the Wading Bird Breeding Potential Index Model and it's performance set output files. NOTE: This model is not utilized after Alternative 3 scenario comparisons. Please see the Wading Bird Foraging Condition Model (files WBFCI___.DOC and WB_MOD__.DOC) for more information.

WBFCI___.DOC - Description of the Wading Bird Foraging Condition Model and it's performance set output files.

WTDBPI__.DOC - Description of the White-tailed Deer Breeding Potential Index Model and it's performance set output files.

Subdirectories:

alt0.to.F2050 - Performance sets for the original September 27 release of Alternative 0 to 2050Base

alt1.to.F2050 - Performance sets for the November 3 release of Alternative 1 to 2050Base

C1995.to.F2050 - Performance sets for the November 3 release of 1995Base to 2050Base

alt3.to.F2050 - Performance sets for the February 2 release of Alternative 3 to 2050Base

alt4.to.F2050 - Performance sets for the March 2 release of Alternative 4 to 2050Base

alt5.to.F2050 - Performance sets for the March 30 release of Alternative 5 to 2050Base

D-C.2 HIGH RESOLUTION HYDROLOGY

Calculation of High Resolution Hydrology in the ATLSS Modeling System

November 1997

Michael Huston and Scott Sylvester
The Institute for Environmental Modeling
University of Tennessee - Knoxville

One of the key features of the ATLSS models is the use of a high resolution hydrology model based on vegetation maps to convert the low resolution hydrologic output of the South Florida Water Management Model (1 water value per 2 x 2 mile cell) to the higher resolution needed to model ecological processes and the distribution of wildlife species. The ATLSS High Resolution Hydrology Model post-processes the output of the South Florida Water Management Model (SFWMM) using an algorithm based on conservation of water volume, and redistributes the water volume over a surface of high resolution topography (ATLSS "pseudotopography") to produce a high resolution map of water depth. This process is repeated on daily timesteps (corresponding to the daily output of the SFWMM) to create a map of water depth across the wetlands of South Florida with over 3000 separate values within each 2 x 2 mile cell (using topography based on the 28.5 meter resolution of a LandSat image).

The first step in calculating high resolution hydrology is processing the output of the SFWMM. This output is provided as daily values of water level for each of the approximately 1700 2 x 2 mile cells of the SFWMM. For the simulation period of 1965-1995 this output is an 88 megabyte file. These data are provided as distance of the water surface from the ground surface (+ or -) and so require a separate file of surface elevations to be converted to absolute elevation above mean sea level. These water surface data are converted to water volume per 2 x 2 mile cell by setting the basal surface of the volume occupied by water in each cell at an elevation 20 meters below the ground surface elevation. This elevation was selected because analysis of SFWMM output for the 31-year simulation period showed that in no cell did the water level ever exceed 20 meters below ground surface, nor 20 meters above ground surface. Thus, each cell has a base elevation for calculation of water volume that is set in relation to its surface elevation. This base elevation is constant throughout the 31 year period. The 40 meter range allows water surface elevations to be stored at 1 millimeter resolution using a "short integer" format in C++.

Because the water surface elevation can be either above or below the ground surface in any cell, water volume calculations must be subdivided into below and aboveground components. Above the ground surface, standing water occupies 100% of the volume defined by the following equation: volume = (water level - ground surface) x the surface area of the cell. Below the ground surface, ground water occupies only a fraction of the total volume, since sediment or bedrock occupy most of the volume (that is, if the ground is "solid"). In the SFWMM, the "water storage capacity" of the bedrock is modeled as varying from region to region across South Florida, but most values are close to 0.2. Thus, ground water is 20% of the volume defined by the following equation: volume = (groundwater level - basal elevation) x the surface area of the cell. When the water level is above the ground surface, calculation of total water volume has both an aboveground and a belowground component.

The ATLSS High Resolution Hydrology Model calculates the volume of water predicted by the SFWMM for each 2 x 2 mile cell for each day of the 31-year simulation period. The primary SFWMM output file used is: daily_stg_minus_lsel.bin. The SFWMM input file from which the bedrock water storage capacities are obtained is: statdta.int95_2. SFWMM data values in feet are converted to metric for use in ATLSS. Thus, the 31 year file of daily water level output is converted to a 31 year file of daily water volume in each of the 1700 cells of the SFWMM "Map" of South Florida.

The second step in calculating high resolution hydrology is redistributing the water volume for each 2 x 2 mile cell over the irregular topographic surface of the ATLSS pseudotopography. Pseudotopography is used to replace the completely flat surface of the SFWMM 2 x 2 mile cell with an undulating surface that corresponds to the topography underlying the vegetation (i.e., the highest areas are hardwood hammocks or pine stands, and the lowest are open water or deep marsh vegetation). The same basic subdivision of volume calculations by surface and subsurface water that was used to calculate water volume from the water surface elevations of the SFWMM is used to convert the water volumes back into surface elevations of water on the undulating landsurface of the pseudotopography. The water surface is assumed to be level across each 2 x 2 mile square of pseudotopography landscape. Consequently, for any particular water surface elevation, some fraction of the total water volume will be surface water (assuming the water level is above the lowest point on the land surface) and the rest will be subsurface water. The ATLSS High Resolution Hydrology Model calculates the water surface elevation for any specific water volume by "balancing" the surface and subsurface volumes to equal the total water volume produced by the SFWMM. This "high resolution hydrology" can potentially estimate water depths for each 28.5 x 28.5 meter area within the region covered by the SFWMM, rather than a single water depth for each 2 x 2 mile area. Thus, the ATLSS High Resolution Hydrology Model converts a low resolution map of 1700 surface water elevation values into a high resolution map with as many as 5.5 million surface water elevation values within the same total area.

The ATLSS High Resolution Hydrology Model provides water depth estimates at spatial scales that are relevant to the vegetation and wildlife species of the Everglades and Big Cypress. Nonetheless, this level of resolution (28.5 m) is not fine enough to detect certain biologically important features, such as alligator holes. For other purposes, such a high resolution is not necessary. Consequently, some of the ATLSS animal models use water data that has been aggregated to 100m or 500m cells, which are based on averages of the 28.5 meter data.

D-C.2.1 Potential Errors in High Resolution Hydrology Calculations

There are three primary sources of error in the daily water depths calculated by the ATLSS High Resolution Hydrology model: 1) Errors in the pseudotopography base map used to calculate water depth; 2) Errors in the daily stage height output of the SFWMM; and 3) Discrepancies between the structure of the SFWMM and the actual physical structure of the South Florida Landscape, as reflected in the vegetation map and the derived pseudotopography. Errors in the base pseudotopography can result from several sources. Obviously, errors in the satellite-based vegetation map will result in errors in any products derived from that map. However, while this map certainly contains a number of misclassified 28.5 x 28.5 m cells, the overall pattern of vegetation is consistent with other maps of South Florida vegetation. So these errors should have relatively little impact on the overall validity of pseudotopography. A second source of error is the hydroperiod parameters used to generate pseudotopography from the vegetation map. These parameters are based on values reported in the literature, and are consistent with the general topographic positions of the major vegetation types found throughout the South Florida wetlands.

More serious sources of error for both pseudotopography, and all water calculations are 2) and 3), listed above. Wherever the output of the SFWMM does not closely match the actual hydrograph that occurs (or would occur) in a particular location, both pseudotopography (based on the "calibration-validation" runs of the SFWMM) and high resolution hydrology may be incorrect at that location.

It is important to note that there is a possibility that high resolution hydrology (HRH) may in some situations actually decrease the errors present in SFWMM output. This occurs because HRH, specifically the underlying pseudotopography, force the shape of the landscape to create hydroperiods appropriate for the vegetation types that are present, while it preserves the water volume predicted by the SFWMM. For example, where the SFWMM predicts a long hydroperiod in an area where the vegetation maps shows only short hydroperiod vegetation types (such as pine and Muhlenbergia), the HRH pseudotopography algorithm will raise the surface of the landscape sufficiently that the appropriate hydroperiods will be experienced by the vegetation. In such a case, the bulk of the water volume will be stored as subsurface water.

Errors in SFWMM output are particularly critical where they result in predicting more favorable conditions than those that would actually occur. This would cause all derivative model runs to overpredict the population density of affected species. In critical habitats, it is important that SFWMM output (specifically the calibration-validation runs on which all empirical model validation will be conducted) be checked against measured stage height data.

The third major source of error results from the inevitable mismatch between a relatively coarse scale model (the 2 x 2 mile grid structure of the SFWMM) and the actual fine-scale patterns of vegetation and control structures on the landscape. The grid structure of the SFWMM requires that physical structures, such as levees, be represented as occurring along the edges of the 2 x 2 mile cells, which produces a "stair-step" approximation of the actual linear structure in the wetlands. This creates a problem for HRH when vegetation on the "down-gradient" side of a levee within a 2 x 2 mile cell is modeled as having water based on the "up-gradient" side of the levee. This problem occurs primarily along the boundaries of the Water Conservation Areas (and is discussed in the Boundaries of the Reporting Units used by ATLSS). This problem results in HRH being incorrect in those areas where SFWMM boundaries do not coincide with actual levees and/or canals. To some degree, HRH and pseudotopography adjust for this type of misalignment by alterning the topographic surface of the landscape so the vegetation experiences the appropriate hydroperiod under calibration conditions. However, this results in a discrepancy between the water depth and hydroperiod predictions of the SFWMM raw output and the water depth and hydroperiods predicted by the High Resolution Hydrology. In such areas of discrepancy, there is a good probability that the HRH results are more accurate that the raw SFWMM output, but this should be checked against actual measurements of topography and hydrographs wherever possible.

One potential solution to the problem of the mismatch between SFWMM model boundaries and the actual boundaries on the landscape is to post-process the SFWMM output into the irregularly shaped cells that correspond to the areas of discrepancy. This would be a substantial programming effort, but would solve this major source of error for all future model runs.

D-C.2.2 Performance measures associated with the ATLSS Hydrology model

In accordance with the ATLSS file naming conventions, each file name will consist of the characters:

"X" or "_" => the Base, typically F for the F2050 base or E for the C1995 base
"X" or "_" => the alternative scenario or base
"HY" => the ATLSS Hydrology Model
"XXXX" => 4 character mnemonic
"."
"PDF" or "TXT" or "DOC" => PDF, tabular text or documentation

Maps

The comparison maps for the ATLSS Hydrology model reflect a graphical representation of the hydroperiod data found in the accompaning tables. For a detailed discussion of the hydroperiod data, see the description of the comparison tables below.

The comparison maps associated with the ATLSS Hydrology model consist of the following files:

File Name	Description
XXHYHCM1.TXT	Comparison map set showing the total area by hydroperiod classes averaged over the years 1985 to 1995 grouped by subregion.
XXHYHCM2.TXT	Comparison map set showing the total area by hydroperiod classes averaged over the five driest years grouped by subregion.
XXHYHCM3.TXT	Comparison map set showing the total area by hydroperiod classes for the driest year grouped by subregion.
XXHYHCM4.TXT	Comparison map set showing the total area by hydroperiod classes averaged over the five wettest years grouped by subregion.
XXHYHCM5.TXT	Comparison map set showing the total area by hydroperiod classes for the wettest year grouped by subregion.
XXHYHCM6.TXT	Comparison map set showing the total area by hydroperiod classes for the average year grouped by subregion.

Time Series Charts None.

Histograms None.

Tables

The high resolution hydrology analysis for the Across Trophic Level System Simulation (ATLSS) consists of a set of tables which compare two hydrology scenarios as provided to our research group by the South Florida Water Management District (SFWMD). The comparisons are broken down into two basic types of files. The first type contains hydroperiod analysis for the vegetation types. The other contains an report on the area in each of 10 hydroperiod classes. These analyses are repeated for each of several regions in South Florida (SF) and for a variety of years or combinations of years.

The comparisons are carried out on a variety of subregions of SF. These regions represent major control and management areas of SF, such as Loxahatchee, the water management areas, and management regions with in The Everglades National Park (ENP) and Big Cypress National Preserve (BCNP).

The comparisons are also broken in to a number of temporal units. The current time groupings are a ten year average from 1985 to 1994, an average of five years which had the highest rain fall (currently 1966, 1968, 1969, 1982, 1983) an average of five years which had the lowest rain fall (currently 1971, 1981, 1988, 1989, 1990), the year with the highest rain fall (1969) the year with the lowest rain fall (1990) and the year with an average rain fall (1977).

The first type of file provides hydroperiod comparison for the vegetation type. Within each region the average hydroperiod is computed for each vegetation type which covers at least 10% of the area of that region. At the top of each table is the name of the region and the total area of that region. Each row of a tables represents the values for a single vegetation type. The columns of each row are defined as follows: The vegetation type index and description, the area of the region covered in that vegetation type, the hydroperiods for the vegetation type under the two scenarios, the difference between the hydroperiods and the percentage difference. The indices represent those used in the Pearlstine vegetation cover map to represent the vegetation types. The vegetation type descriptions are those used by The Nature Conservancy (TNC) for the South Eastern United States. Hydroperiods have units of days, and the areas are listed in Km.

The second type of table gives the area covered in each region by each of twelve hydroperiod classes. The top of the table gives the region name and the total area of the region. Each row of the tables contains the information about a single hydroperiod class. The columns of each row are defined as follows: The first column contains the range of hydroperiod which defines the hydroperiod class, the next two are give the area of the listed region which has a hydroperiod with in the range of values for that class for each of the scenarios being compared and the last column gives the difference between these two values.

The mnemonic section of the file names are composed as follows:

"XX" = P1, P2, P3, P4, P5 => the Time Period
"XX" = HC, VT => Hydrology Class, Vegetation Type

The performance measure tables associated with the ATLSS Hydrology model consist of the following files:

File Name	Description
XXHYVTP1.TXT	Comparison tables set showing the total area of significant vegetation types averaged over the years 1985 to 1994 grouped by subregion.
XXHYVTP2.TXT	Comparison tables set showing the total area of significant vegetation types averaged over the five driest years grouped by subregion.
XXHYVTP3.TXT	Comparison tables set showing the total area of significant vegetation types for the driest year grouped by subregion.
XXHYVTP4.TXT	Comparison tables set showing the total area of significant vegetation types averaged over the five wettest years grouped by subregion.
XXHYVTP5.TXT	Comparison tables set showing the total area of significant vegetation types for the wettest year grouped by subregion.
XXHYVTP6.TXT	Comparison tables set showing the total area of significant vegetation types for the average year grouped by subregion.
XXHYHCP1.TXT	Comparison tables set showing the total area by hydroperiod classes averaged over the years 1985 to 1995 grouped by subregion.
XXHYHCP2.TXT	Comparison tables set showing the total area by hydroperiod classes averaged over the five driest years grouped by subregion.
XXHYHCP3.TXT	Comparison tables set showing the total area by hydroperiod classes for the driest year grouped by subregion.
XXHYHCP4.TXT	Comparison tables set showing the total area by hydroperiod classes averaged over the five wettest years grouped by subregion.

XXHYHCP5.TXT	Comparison tables set showing the total area by hydroperiod classes for the wettest year grouped by subregion.
XXHYHCP6.TXT	Comparison tables set showing the total area by hydroperiod classes for the average year grouped by subregion.

D-C.2.3 F2050 (Revised) vs. C1995 (Revised)

The ATLSS models and breeding potential indices are driven by input data from the South Florida Water Management Model (SFWMM). These data, which are provided as daily water depth for each 2 x 2 mile area in the region covered by the model, are processed by the ATLSS landscape model into high resolution hydrology that is based on a high resolution topographic map created from a high resolution vegetation map (see section 1.1 above or HYDRO___.DOC for a more detailed description of high resolution hydrology and pseudotopography). The ATLSS landscape model redistributes the water from the SFWMM across the landscape in a way that produces hydroperiods that are appropriate for the vegetation types that occur in a specific area. The high resolution hydrology patterns may appear quite different from the output of the SFWMM, since the high resolution hydrology produces a mosaic of wet and dry areas (or deep and shallow water) within each 2 x 2 mile area that is represented in the SFWMM output as a uniform water depth (or completely dry) over the entire 2 x 2 mile area.

D-C.2.3.1 SFWMM Output Comparisons

In the raw output from the SFWMM for the C1995 and F2050 scenarios the differences in water depth form clear and stable patterns. C1995 generates increased water depth relative to F2050 in WCA-1, most of WCA-3A South, and a small region located along the boundary between the East Panhandle and South Taylor Slough. C1995 generates decreased water depth relative to F2050 in WCA-2A, WCA-2B, WCA-3B, the Rotenberger-Holeyland area, the north end of WCA-3A and through the remnant water way including Shark River Slough, East Slough, the northern portion of Taylor Slough and the area surrounding these sloughs. The region in WCA-1 experiences increased water depth under C1995 relative to F2050 in all years except the first year of simulation, 1969. In this year the water depth in WCA-1 is deeper under F2050. The differences in water depth in WCA-1 between C1995 and F2050 shows a smoothly graded pattern from large differences along the southern boundary of WCA-1 and smallest difference in the northern most corner. This pattern is present in all years with year to year variations in the range of differences. In WCA-3A, C1995 generates a region of increased water depth relative to F2050 which forms a band from the south west corner to the north east corner and is parallel to the L-67 levies. This pattern of increased water depth is present during the entire 31 year simulation time period. During some years WCA-3B and the Dwarf Cypress/Lostmans Pines area, which are adjacent to WCA-3A, experience increased water depths under C1995 relative to F2050, though typically these areas have lower water depths under C1995. The southern region of increased water depth under C1995 in the East Panhandle boundary is present in all years with variations in extent and peak value from year to year. C1995 also predicts a number of regions of lower water depths relative to F2050. The Rotenberger-Holeyland area and the northern portion of WCA-3A experience decreased water depth under C1995 relative to F2050 over the entire 31 year time frame. In most years the differences between C1995 and F2050 in these areas are significant. However, in years such as 1990, the spatial extent of these areas of lower C1995 water depths are contracted and cover only the Rotenberger-Holeyland area and a small portion of the north east corner of WCA-3A. WCA-2A and WCA-2B experience decreased water depths under C1995 relative to F2050 over most of the 31 years. Within WCA- 2A the greatest differences between the scenarios occurs most commonly along the south and south west borders, and the smallest differences appear along the border shared with WCA-1 in the north east. Between these boundaries the differences generally form a smooth gradient from south west to north east. In a very few years, such as 1971 and 1973, there is a departure from this pattern. During these years, the northern third of WCA-2A has decreased water depths under C1995 relative to F2050, while the lower two-thirds experiences an increase in water depth under C1995. During other years, such as 1979 and 1988 the pattern of gradation in WCA-2A described earlier is still present, however, in these years the water depth along the north east border of WCA-2A is deeper and the south west border is given less water under C1995 as compared to F2050. Except for a three year run from 1988 to 1990, the water depths in WCA-2B are significantly lower under C1995 as compared to F2050. During this three year run, the difference between C1995 and F2050 do not form any strong patterns. While the region still experiences slightly decreased water depth under C1995, some cells have increased water depth during some of the years. Water depths in WCA-3B are lower under C1995 relative to F2050 for most of the years of the scenario run. For most of these years of decreased water depth there are larger differences in the northern portion and smaller difference in the southern portion, though during several years the differences are consistent over the entire area. WCA-3B has regions of increased water depths under C1995 during a few years. For some of the years the locations of increase are small and appear along the border formed by the L-67 levies. During some years, such as 1979, all of WCA-3B experiences increased water depths under C1995 relative to F2050. Through most of the area within the Everglades National Park (ENP), including all of Shark River Slough, the northern portion of Taylor Slough and most of East Slough, C1995 generates decreased water depths as compared to F2050 over all of the 31 year time period. The largest difference is water depth within this region typically occur through the center of Shark River Slough, with differences becoming smaller as distance from the center of the Slough increases. During some years, such as 1995, the largest difference between C1995 and F2050 are found along the eastern edge of the ENP.

Additionally there is a small region between the East and West Panhandle which experience decreased water depth under C1995 relative to F2050 during many of the years of the scenario. Over most of Big Cypress National Preserve (BCNP) the differences between C1995 and F2050 are small and scattered through the region. C1995 is slightly dryer that F2050 within this region over all the years of the scenario, but the dryer locations are scattered through the area, are not consistent from year to year, and do not form a clear pattern of drying.

D-C.2.3.2 ATLSS High Resolution Hydrology Output Comparison

The 1985-1994 10-year average hydroperiod analysis (Figure FEHYHPM1.PDF) shows a pattern of longer hydroperiod created by C1995 in WCA-1, most of WCA-2A, most of WCA-3A, WCA-3B, the Dwarf Cypress/Lostmans Pines area and in a region which lies along the border between South Taylor Slough and the Western Panhandle. Hydroperiods in these regions are lengthened between 1 to 14 weeks relative to F2050. The pattern of increased hydroperiod in WCA-2A occurs throughout most of the region except for a small patch in the northern corner. In this corner the hydroperiod generated by C1995 is shorter than the hydroperiod generated by F2050. The region of increased hydroperiod in WCA-3A is present across most of the region except two small regions in the north east and north west corners. In these small regions the hydroperiod generated by C1995 is shorter than the hydroperiod generated by F2050. The range of lengthened hydroperiods generated by C1995 in WCA- 1 is consistent across the entire region. The range of lengthened hydroperiod generated by C1995 in WCA-2A has only small variations. The regions of lengthened hydroperiod which covers most of WCA-3A, WCA-3B and the Dwarf Cypress/Lostmans Pines area contains a great deal of variability in the hydroperiod differences generated. There are regions of varying size located throughout the region which have significantly lengthened hydroperiod under C1995 relative to F2050. These sub-regions correspond to various structures within WCA-3A. Some sub-regions reflect tree islands within WCA-3A, while others reflect the presence of the C-304 canal. There is also a region parallel to the L-67 levies of hydroperiods which are moderately lengthened by C1995 relative to F2050. A small region of C1995 lengthened hydroperiod is centered approximately mid-way long the boundary between the South Taylor Slough and the West Panhandle with difference in hydroperiods between C1995 and F2050 becoming smaller as distance from the center of the pattern increases. Over the 10-year average there area several regions where the hydroperiod generated my C1995 is shorter than the hydroperiod generated by F2050. A small region in the northern section of WCA-2A and two regions in the north east and north west corners of WCA-3A all have shorter hydroperiods under C1995 relative to F2050. Additionally WCA-2B is also given a shorter hydroperiod under C1995 relative to F2050, though the differences in the predicted hydroperiods are not as large in this region as in other locations. There is also a large region in the southern portion of the study area, including Shark River Slough, North Taylor Slough and East

Slough, where the hydroperiod predicted by C1995 is shorter than the hydroperiod predicted by F2050. In this southern region the differences through Shark River Slough are relatively small, representing a difference of only 1-2 weeks. In the regions directly to the north and south of Shark River Slough, the differences are much larger. Of all the regions for which C1995 predicts shortened hydroperiod relative to F2050, the two in the north of WCA-3A show the largest differences with the north east corner displaying a moderately size region of consistently large differences. In addition to these regions of shortened hydroperiod, there is a small region in the eastern section of the East Panhandle which show a modest shortening of hydroperiod under C1995 as compared to F2050.

The basic pattern of long and short hydroperiod predicted by C1995 relative to F2050 seen in the 10-year average is consistent across each of the rain fall year conditions used in this analysis. During all the rain fall conditions, C1995 predicts lengthened hydroperiod in WCA-1, most of WCA-3A, and the small region along the common border between South Taylor Slough and the West Panhandle. In WCA-1 under low and average rain fall conditions (Figures FEHYHPM2.PDF, FEHYHPM3.PDF and FEHYHPM6.PDF), C1995 generates hydroperiods which are not only longer than those generated by F2050, but the difference in the hydroperiods is greater than the differences shown in the 10-year average. During the wet conditions (FEHYHPM4.PDF and FEHYHPM5.PDF) the hydroperiods predicted by C1995 are still longer than those of F2050 but the differences for WCA-1 are diminished, and in fact show sections where there are no perceivable difference in hydroperiod. The pattern of lengthened hydroperiod generated by C1995 relative to F2050 in WCA-3A South is also present under all rain fall conditions. Under the lowest rain fall conditions, 1990, (Figure FEHYHPM3.PDF) the patterns is reduced both in extent and in maximum difference. The region which was predicted as having longer hydroperiod under C1995 relative to F2050 is broken in to two pieces, divided by a band, showing no difference in hydroperiod, which cuts across the center of WCA-3A and is parallel to the L-67 levies. The small region of C1995 lengthened hydroperiod along the border between South Taylor Slough and the West Panhandle is also present under all rain fall conditions with some variation in extent, exact location and peak value during the different rain fall conditions. In WCA-2A the pattern of differences between C1995 and F2050 predicted hydroperiods changes under varying rain fall conditions. Under the low rain fall conditions (Figure FEHYHPM2.PDF and FEHYHPM3.PDF) the pattern of differences is similar to the pattern seen in the 10-year average rain fall. Most of the region is given a longer hydroperiod under C1995 relative to F2050, with a small section in the north where C1995 generates shorter hydroperiods. Under low rain fall conditions the difference between C1995 and F2050 are larger than those seen in the 10-year average. Under high rain fall conditions (Figure FEHYHPM4.PDF and FEHYHPM5.PDF) the pattern of hydroperiod differences between C1995 and F2050 almost disappears in WCA-2A and WCA-2B. Under average rain fall conditions (Figure FEHYHPM6.PDF) C1995 predicts a region of significantly lengthened hydroperiod within WCA-2A along the boundary separating WCA-2A and WCA-1. Immediately to the south of this structure, extending to the border between WCA-2A and WCA-2B, there is a region where C1995 generates shorter hydroperiods relative to F2050. Along the north west border shared with the Everglades Agricultural Area (EAA) C1995 and F2050 generate hydroperiods which are identical. Within WCA-2B the two scenarios generate similar hydroperiod, with C1995 predicting slightly shorter hydroperiods along the eastern border under some conditions. Only under the lowest rain fall conditions (Figure FEHYHPM3.PDF) does C1995 predict longer hydroperiod relative to F2050 for WCA-2B. Shark River Slough, North Taylor Slough, the Ten Mile Marl and the surrounding areas tend to have shorter hydroperiods under C1995 relative to F2050. Under the highest rain fall conditions (Figures FEHYHPM4.PDF and FEHYHPM5.PDF) the two scenarios predict nearly identical hydroperiod for most of Shark River Slough, though the surrounding areas still have a shorter hydroperiod under C1995 relative to F2050. Under low and average rain fall conditions (Figures FEHYHPM2.PDF, FEHYHPM3.PDF and FEHYHPM6.PDF) small patches appear within Shark River Slough for which C1995 predicts a longer hydroperiod relative F2050. The two areas in north WCA-3A for which C1995 predicts shorter hydroperiods relative to F2050 are also present under all rain fall conditions. Under low rain fall conditions (Figure FEHYHPM2.PDF and FEHYHPM3.PDF) the western of these two areas is diminished in spatial extent and peak value, nearly disappearing during the lowest rain fall year, 1990. During the years of highest rain fall become larger and more intense filling most of WCA-3A north of I-75. Additionally, there is a small regions along the border between the East and West Panhandle where C1995 predicts shorter hydroperiods on average than F2050. This region is present under the 10-year average, 5 lowest rain fall average and the wettest rain fall conditions (Figures FEHYHPM1.PDF, FEHYHPM2.PDF, FEHYHPM4.PDF and FEHYHPM6.PDF). This small region disappears during the lowest rain fall year, 1990 (Figure FEHYHPM3.PDF) and is enhanced during the highest rain fall years.

Overall the pattern of difference in hydroperiod predicted by C1995 and F2050 is consistent across all rain fall conditions. A pattern of hydroperiod lengthened under C1995 relative to F2050 is present throughout much of the northern portion of the study area. WCA-1, most of WCA-2A and most of WCA-3A are given lengthened hydroperiod under C1995 relative to F2050. Two regions in the northern portions of WCA-3A are given shortened hydroperiods by C1995 relative to F2050 under all rain fall conditions. WCA-2B is given shorter hydroperiods under C1995 under most rain fall conditions. WCA-2A is given longer or equal hydroperiods by C1995 under most rainfall conditions. An additional region in the southern section of the study area along the border between the West Panhandle and South Taylor Slough is given a longer hydroperiod by C1995 under all rain fall conditions. The pattern of C1995 shortened hydroperiod in the periphery of Shark River Slough of the study area is also consistent across all rainfall conditions.

D-C.2.4 Alternative A vs. F2050 (Revised)

D-C.2.4.1 SFWMM Output Comparisons

In the raw output from the SFWMM the differences between ALT-A and F2050 form patterns of increased and decreased water depth which are consistent over the most of the 1965 to 1995, 31-year time period. For part of the study area including WCA-1, WCA-2A, WCA-2B, Shark River Slough, Taylor Slough, Long Pine Key, West Panhandle, and in several areas surrounding those, ALT-A predicts higher water depths relative to F2050 in almost every year of the simulation time period. These differences are most pronounced in the central portion of Shark River Slough. There are some years (1965, 1981, 1984, 1986, 1993, 1994) for which the pattern for most of WCA-2A and WCA-2B is reversed, with lower water depths predicted by ALT-A. In a few other years (1966, 1968, 1976, 1977, 1995), portions of WCA-2A have a higher predicted water for ALT-A, while other portions have lower predicted water. In several areas including most of the Rotenberger/Holeyland area, WCA-3A South along the L-67 levees, the eastern portion of WCA-3A north of I-75 (WCA-3A North), most of the East Slough, the East Panhandle, and portions of BCNP, ALT-A predicts water depths which are lower for most or all of the 31-year time period. In some years (1965, 1972, 1973, 1981, 1982, 1986, 1994, 1995) the lower water depths predicted by ALT-A expand to cover essentially all of WCA-3A and 3B, while in other years the region of ALT-A lowered water is restricted to the southern portions of WCA-3A South and the eastern portions of WCA-3A North. The pattern in WCA-3B is complex, with some years having ALT-A increased water depths, other years decreases in these depths relative to F2050, and other years having a mixer pattern. ALT-A predicts lower water depths in the eastern half of the Rotenberger/Holeyland area for every year except 1984 when most of the area is given higher water depths by ALT-A relative to F2050. In approximately one-third of the years, the western most portion of the Rotenberger/Holeyland area is given higher water depths under ALT-A relative to F2050. The pattern predicted for WCA-3A North is quite variable from year to year, with some years (1967, 1970, 1974, 1979, 1989, 1992) having ALT-A increased water depths, other years (1971, 1972, 1986, 1994, 1995) having mostly ALT-A decreased water depths, and the remaining having a mixed pattern throughout the area. The pattern of decreased water depth ALT-A predicts as compared to F2050 along the L-67 levees through the East Slough and Dwarf Cypress/Lostmans Pine areas is present during most every year (not in 1967, 1970, 1974, 1978, 1989) of the simulation time period. In the years when this pattern is broken East Slough and the surrounding area still have shorter hydroperiods under ALT-A relative to F2050, but the southern end of WCA-3A South is given longer hydroperiods. Over time changes in the pattern of lowered water in the East Slough and surrounding areas show up as an increase in the spatial extent of ALT-A lowered water depths from the south eastern portion of the pattern into southern BCNP. The pattern in BCNP is a complex intermingling of small areas with increased water depths in ALT-A relative to F2050 and small areas with decreases.

D-C.2.4.2 ATLSS High Resolution Hydrology Output Comparison

In the 1985 to 1994, 10-year average, hydroperiod analysis (Figure FAHYHPM1.PDF) most of the study area is given either an increased hydroperiod by ALT-A relative to F2050, or there is no significant difference. WCA-1, WCA-2A, WCA-2B, WCA-3B, Shark River Slough, Taylor Slough, and Long Pine Key are given longer hydroperiods by ALT-A relative to F2050 during the 10-year average rain fall condition. Of these areas the eastern border of the study area from WCA-3B south through Northern Taylor Slough shows the largest increase in hydroperiod under ALT-A relative to F2050. The only regions with shortened hydroperiods predicted for ALT-A are the East Slough area, small portions of WCA-3A North, and portions of the Western Panhandle. Most of WCA-3A South, and BCNP are assigned equivalent hydroperiods by ALT-A and F2050. A few of the above described patterns of lengthened and shortened hydroperiod are present under most or all of the other rain fall conditions. Under all rain fall conditions the regions in North Taylor Slough and most of WCA-3B are given longer hydroperiods under ALT-A relative to F2050. The only exception within these areas is in a small region in the south east corner of WCA-3B where, during the high rain fall condition (Figures FAHYHPM4.PDF and FAHYHPM5.PDF), the two scenarios predict similar hydroperiods. Under all but the high rain fall conditions (Figures FAHYHPM4.PDF and FAHYHPM5.PDF) all of Shark River Slough is given longer hydroperiods by ALT-A relative to F2050. During the high rain fall conditions, Shark River Slough along with much of WCA-1, WCA-2A, and WCA-2B are all given similar hydroperiods by both ALT-A and F2050. For all rain fall conditions in the central portion of WCA-3A South, ALT-A and F2050 predict similar hydroperiods. Around the periphery of this region there is no difference or an increase in hydroperiod under ALT-A for most rain fall conditions. Only during the average rain fall year, 1977, (Figure FAHYHPM6.PDF) does ALT-A predict shorter hydroperiods relative to F2050 around the perimeter of WCA-3A South. BCNP receives equivalent predicted hydroperiods by the two scenarios for all rain fall conditions. During all but the average rain fall conditions most of East Slough, the northern part of the 10-Mile Marl and small portions of the surrounding areas receive shorter hydroperiods under ALT-A relative to F2050. For the average rain fall year, 1977, (Figure FAHYHPM6.PDF) most of East Slough has the same hydroperiod under ALT-A and F2050. The small region of ALT-A shortened hydroperiod in the West Panhandle persists under all rain fall conditions, though there are small changes in the spatial extent and the character of the immediately surrounding areas during the various rain fall conditions. The patterns of long and short hydroperiod predicted by ALT-A relative to F2050 for WCA-2A and WCA-3A North are not consistent across the various rain fall conditions. For most of WCA-

2A, ALT-A predicts long hydroperiods during the 10-year average and the average of the five lowest rain fall conditions. During the lowest rain fall year, 1990, (Figure FAHYHPM3.PDF) ALT-A predicts longer hydroperiods around the perimeter of WCA-2A relative to F2050 and similar hydroperiods in the center of the conservation area. For the high rain fall conditions (Figure FAHYHPM4.PDF and FAHYHPM5.PDF) most of WCA-2A is given equivalent hydroperiods by both scenarios with only a small region of ALT-A lengthened hydroperiod along the north eastern border shared with WCA-1. For the average rain fall year, 1977, (Figure FAHYHPM6.PDF) most of WCA-2A is given shorter hydroperiods by ALT-A with a few scattered areas of equal or longer hydroperiod. The hydroperiod patterns within WCA-3A North are variable both in location and under what rain fall conditions the patterns arise. A thin band within WCA-3A North which follows the C-304 canal is given shorter hydroperiods under all of the rain fall conditions though there is a great deal of variability in the extent and intensity of the values along this band. During the other rain fall conditions hydroperiods within this region are variable. For the average of the five highest rain fall conditions (Figure FAHYHPM4.PDF) much of WCA-1 is still given longer hydroperiods by ALTA relative to F2050. Under the highest rain fall conditions, 1969, (Figure FAHYHPM5.PDF) the two scenarios predict similar hydroperiods over most of WCA-1, leaving only a small area in the north for which ALT-A predicts longer hydroperiods relative to F2050.

Overall the general patterns predicted for ALT-A hydroperiods relative to F2050 are consistent spatially with lengthened hydroperiod predicted by ALT-A for Taylor Slough, much of Shark River Slough, WCA- 3B, and WCA-1. ALT-A predicts shortened hydroperiods in East Slough and portions of the Western Panhandle and WCA-3A North. For most of BCNP and WCA-3A South, ALT-A and F2050 have similar predicted hydroperiods. The above patterns have some spatial variation based upon rain fall conditions.

D-C.2.5 Alternative B vs. F2050 (Revised)

D-C.2.5.1 SFWMM Output Comparisons

In the raw output from the SFWMM the differences between ALT-B and F2050 form patterns of increased and decreased water depth which are consistent over the most of the 1965 to 1995, 31-year time period. For most of the study area including WCA-1, WCA-3B, most of WCA-3A south of I-75 (WCA-3A South), most of WCA-2A, Shark River Slough, Taylor Slough, Long Pine Key, East and West Panhandle, part of eastern Big Cypress National Preserve (BCNP) and in several areas surrounding those named ALT-B predicts higher water depths relative to F2050 in almost every year of the simulation time period. In a small region along the border between East and West Panhandle ALT-B predicts higher water levels relative to F2050 which are significantly greater than those in the immediately surrounding areas. In WCA-3A South ALT-B predicts higher water depths relative to F2050 for most of the northern portion of the conservation area during all of the 31-year time period except 1995. A region within WCA-3A South lying along the L-67 levees and the southern border of the conservation area is predicted by ALT-B as having lower water depths relative to F2050. This band of lowered ALT-B water depths is connected to a region of lower water depths in the East Slough area. The pattern of difference between the two scenarios is less distinctive and less consistent in WCA-2A. Most frequently the southern half of WCA-2A is given lower water depths and the northern half higher water depths by ALT-B relative to F2050. However, during several years all or most of WCA- 2A is given higher water depths under ALT-B as in 1968, 1973 and 1982. Occasionally all of WCA-2A is given lower water depths by ALT-B relative to F2050 as in 1965 and 1983. In several areas including WCA-2B, the eastern half of the Rotenberger/Holeyland area, WCA-3A South along the L-67 levees, most of WCA-3A north of I-75 (WCA-3A North), most of the Dwarf Cypress/Lostmans Pine area, East Slough and a small region south of the Panhandle areas ALT-B predicts water depths which are lower for most or all of the 31-year time period. All of WCA-2B is given lower water depths by ALT-B relative to F2050 during every year except 1974, 1975 and 1988 to 1990 inclusive. During these years ALT-B predicts higher water depths relative to F2050 over the most or all of WCA-2B. ALT-B predicts lower water depths in the eastern half of the Rotenberger/Holeyland area for every year except 1984 when most of the area is given higher water depths by ALT-B relative to F2050. The western most portion of the Rotenberger/Holeyland area is most frequently given higher water depths under ALT-B relative to F2050. Relative to F2050, ALT-B predicts lower water depths in the north east corner of WCA-3A North. During many years this area of lower ALT-B water covers most or all of WCA-3A North. Under some conditions, such as those experienced in 1980 through 1982 the region of lowered water depths in WCA-3A North extends southward along the eastern border of the conservation area and connects with the area of lower ALT-B water depths along the L-67 levees. For only a few years, such as 1970, ALT-B predicts higher water depths relative to F2050 over most of WCA- 3A North. The pattern of decreased water depth ALT-B predicts as compared to F2050 along the L-67 levees through the East Slough and Dwarf Cypress/Lostmans Pine areas is present during every year of the simulation time period. Over time this pattern demonstrates very small changes in character which mostly show up as an increase in the spatial extent of ALT-B lowered water depths from the south eastern portion of the pattern into southern BCNP. The only region within the study area for which ALT-B and F2050 predict similar water depths is in the western portion of BCNP. This region of equal water depths is present at this location for most or all of the 31-year time period.

D-C.2.5.2 ATLSS High Resolution Hydrology Output Comparison

In the 1985 to 1994, 10-year average, hydroperiod analysis (Figure FBHYHPM1.PDF) most of the study area is given an increased hydroperiod by

ALT-B relative to F2050. WCA-1, WCA-2A, west central WCA-3A, WCA-3B, Shark River Slough, Taylor Slough, Long Pine Key and the West Panhandle area are given longer hydroperiods by ALT-B relative to F2050 during the 10-year average rain fall condition. Of these areas the region within WCA-3A, the eastern border of the study area from WCA-3B south through Northern Taylor Slough and a small region in the West Panhandle show the largest increase in hydroperiod under ALT-B relative to F2050. A nearly continuous band from the north east corner of WCA-3A, along the eastern border of WCA-3A, the L-67 levees, the southern border of WCA-3A and through the East Slough area is given shorter hydroperiods by ALT-B relative to F2050 during the 10- year average rain fall conditions. Over most of it's length the band is separated from the region of lengthened hydroperiod in central WCA- 3A by an area for which ALT-B and F2050 predict equivalent hydroperiods. The northern most part of the band, in the north east corner of WCA-3A, covers most of WCA-3A North, and shows the largest decrease in hydroperiod predicted by ALT-B relative to F2050. Two small additional areas in the eastern most portion of WCA-2B and in the southern part of the West Panhandle area are also given shorter hydroperiods under ALT-B relative to F2050. A few of the above described patterns of lengthened and shortened hydroperiod are present under most or all of the other rain fall conditions. Under all rain fall conditions the regions in west central WCA-3A, most of WCA-3B, North Taylor Slough and in the West Panhandle are given longer hydroperiods under ALT-B relative to F2050. Under all but the high rain fall conditions (Figures FBHYHPM4.PDF and FBHYHPM5.PDF) all of WCA-1 is given longer hydroperiods by ALT-B relative to F2050. Under the high rain fall conditions parts of WCA-1 are given similar hydroperiods by both ALT-B and F2050. For the average of the five highest rain fall conditions (Figure FBHYHPM4.PDF) most of the WCA-1 is still given longer hydroperiods by ALT-B relative to F2050 with only a small region along the south western border where the two scenarios predict similar hydroperiods. Under the highest rain fall conditions, 1969, (Figure FBHYHPM5.PDF) the two scenarios predict similar hydroperiods over most of WCA-1, leaving only a small area in the north for which ALT-B predicts longer hydroperiods relative to F2050. All of WCA-3B is given longer hydroperiods by ALT-B relative to F2050 under all but the highest rain fall conditions. During the highest rain fall conditions, 1969, (Figure FBHYHPM5.PDF) a small part of WCA-3B in the south east corner is given similar hydroperiods by both ALT-B and F2050. Under all rain fall conditions ALT-B predicts shortened hydroperiod in the north eastern portion WCA-3A North. There is some variation in this pattern under the various rain fall conditions, most notably during the high rain fall conditions (Figures FBHYHPM4.PDF and FBHYHPM5.PDF) when the spatial extend and peak value of the pattern of ALT-B lowered hydroperiod is decreased. The reduction becomes most extreme during the highest rain fall year, 1969, (Figure FBHYHPM5.PDF) when only a small area in the center of WCA-3A North is predicted by ALT-B as having shorter hydroperiods relative to F2050, the rest of the conservation area being given the same hydroperiods by both scenarios. For all but the lowest rain fall conditions ALT-B predicts lower hydroperiods in the East Slough area. During the lowest rain fall conditions, 1990, (Figure FBHYHPM3.PDF) ALT-B and F2050 predict similar hydroperiod in East Slough with a few scattered locations throughout the area for which ALT-B still predicts shorter hydroperiods. Under all but the highest rain fall conditions, 1969, (Figure FBHYHPM5.PDF) ALT-B predicts shorter hydroperiods relative to F2050 along the L-67 levees.

Under all but the low rain fall conditions ALT-B predicts shorter hydroperiods than those predicted by F2050 for most or all of WCA-2B. During the low rain fall conditions (Figures FBHYHPM2.PDF and FBHYHPM3.PDF) ALT-B predicts longer hydroperiods within WCA-2B. Under the average rain fall conditions, 1977, (Figure FBHYHPM6.PDF) ALT-B predicts shorter hydroperiods for almost all of WCA-2B relative to F2050. In WCA-2A ALT-B predicts longer or equivalent hydroperiods relative to F2050 during the various rain fall conditions. For the 10- year average, and the average of the five lowest rain fall conditions (Figures FBHYHPM1.PDF and FBHYHPM2.PDF) ALT-B predicts longer hydroperiod for most of WCA-2A relative to F2050 with a small region in the south central portion of the area for which the two scenarios predict equivalent hydroperiods. During the lowest, the high and average rain fall conditions (Figures FBHYHPM3.PDF through FBHYHPM6.PDF) the two scenarios predict similar hydroperiods for most of WCA-2A. Under these rain fall conditions a few areas near the borders of the conservation area are still predicted has having longer hydroperiod by ALT-B relative to F2050. Through Shark River Slough the pattern of long and short hydroperiod is not consistent over the various rain fall conditions. For the 10-year average, the five lowest and the average rain fall conditions (Figures FBHYHPM1.PDF, FBHYHPM2.PDF, FBHYHPM6.PDF) most of Shark River Slough is given longer hydroperiods by ALTB as compared to F2050. During the high rain fall conditions (Figures FBHYHPM4.PDF, FBHYHPM5.PDF) most of the slough is given equivalent hydroperiods by both scenarios. Finally under the lowest rain fall conditions (Figure FBHYHPM3.PDF) the northern end of the slough is given equal hydroperiod by the two scenarios, the central portion is given lower hydroperiod by ALT-B and the southern end is given longer hydroperiod by ALT-B as compared to F2050. In the Long Pine Key area and in South Taylor Slough ALT-B gives equal or longer hydroperiods under all rain fall conditions relative to F2050. Under the low rain fall conditions (Figures FBHYHPM2.PDF, FBHYHPM3.PDF) Long Pine Key, South Taylor Slough and parts of the surrounding areas are given equivalent hydroperiods by both scenarios. During the high and average rain fall conditions (Figures FBHYHPM4.PDF though FBHYHPM6.PDF) only part of Long Pine Key is given longer hydroperiods by ALT-B as compared to F2050, with the central portion of Long Pine Key and most of South Taylor Slough area still given similar hydroperiods by the scenarios.

Overall the general patterns predicted for ALT-B hydroperiods relative to F2050 are consistent spatially with lengthened hydroperiod predicted by ALT-B for central Shark River Slough, WCA-3B, central western portion of WCA-3A South, and WCA-1. ALT-B predicts shortened hydroperiods along a band from northeastern portion of WCA-3A North, along the L-67 levees, and through the southern portion of WCA-3A South into East Slough. For most of BCNP ALT-B and F2050 have similar predicted hydroperiods. The above patterns have some spatial variation based upon rainfall conditions.

D-C.2.6 Alternative C vs. F2050 (Revised)

D-C.2.6.1 SFWMM Output Comparisons

In the raw output from the SFWMM for the ALT-C and F2050 scenarios the differences in water depth show clear and stable patterns. ALT-C generates increased water levels relative to F2050 in WCA-1, most of WCA-3A south of I-75, WCA-3B, and most of the Everglades National Park (ENP) including Shark River Slough, Taylor Slough, Long Pine Key, and the East and West Panhandle areas. ALT-C predicts lower water levels in parts of the Rotenberger-Holeyland area, a portion of WCA-3A north of I-75, most of the southern end of WCA-2A, WCA-2B, East Slough and a small region south of East and West Panhandle areas. In Big Cypress National Preserve (BCNP) the differences between ALT-C and F2050 show only nominal differences in water depth between the two scenarios. For most of BCNP ALT-C predicts deeper water with scattered areas of decreased water depth relative to F2050. These differences in BCNP do not form a consistent pattern of wetting or drying over the 31-year time period. These patterns of increased and decreased water depth within the study area are consistent across the entire 1965-1995 time period with some year to year variation. In almost all years simulated by the SFWMM ALT-C predicts lower water depths relative to F2050 in a contiguous region which includes the eastern half of the Rotenberger-Holeyland area, a band in WCA-3A north of I-75, the southern end of WCA-2A and WCA-2B. During all years the largest decrease in water depths between ALT-C and F2050 occur in the Rotenberger-Holeyland area and WCA-2B. The band of decreased water depths predicted by ALT-C relative to F2050 in WCA-3A north of I-75, which extends from the north east corner of WCA-3A south west into the conservation area, is present in almost every year. In some years, such as 1970, the band disappears and ALT-C predicts increased water depths relative to F2050 for most of WCA-3A north of I-75. In other years the spatial extent of the band increases and ALT-C predicts deeper water relative to F2050 for most of WCA-3A north of I-75. Relative to F2050, ALT-C predicts lower water depths in the eastern portion of the Rotenberger-Holeyland area for almost all of the 31-year time period. For several of these years ALT-C predicts lower water depths for all of the Rotenberger-Holeyland area and for two years, 1983 and 1984, ALT-C predicts high water depths relative to F2050 for most of the area. In most years ALT-C predicts lower water levels in the southern part of WCA-2A and higher water levels in the northern part. Though the pattern within WCA-2A is present in almost every year, there are large variations in the extent of increased and decreased water depths produced by ALT-C relative to F2050.

During some years, such as 1983, nearly all of WCA-2A has decreased water depths under ALT-C relative to F2050; while in 1988 ALT-C predicts higher water depths for the entire area. Over most the 31-year simulation period WCA-2B is given lower water depths under ALT-C relative to F2050 and remains a region in which ALT-C predicts the greatest deficit of water relative to F2050. Only during 1974, 1975 and 1988-1990 do the ALT-C predictions for WCA-2B change, giving the region lower water depths relative to F2050. ALT-C also predicts lower water depths in the East Slough area and south of East and West Panhandle for most of the 31-year simulation time period. The area of decreased water depth in East Slough predicted by ALT-C relative to F2050 is present in every year from 1965 to 1995. During this time the surrounding areas to the north in the Dwarf Cypress/Lostmans Pine area, to the south in the 10-Mile Marl area, and to the north east in the southern end of WCA-3A all experience episodes of lowered water depth under ALT-C relative to F2050. In the southern most end of the ENP a small area south of the East and West Panhandle areas is predicted by ALT-C to have lower water depths relative to F2050 for every year of the simulation time period. Occasionally, ALT-C predicts additional surrounding areas to the west and north as having lower water depths relative to F2050. The increased water levels predicted by ALT-C relative to F2050 for WCA-1, WCA-3A south of I-75, WCA-3B, and the ENP are present over most of the 31-year simulation period. During the simulation period, almost all of WCA-1 is given deeper water depths under ALT-C relative to F2050. During a few, very rare occasions a small area in the northern end of the conservation area is given lower water depths relative to F0205. From 1965 to 1995 the largest areas of increase under ALT-C occur along Shark River Slough and in the eastern portion of WCA-3A parallel to the L-67 levies. Most of the ENP is predicted as having deeper water depths under ALT-C relative to F2050, though as times parts of Shark River Slough at the southern reaches of the park are given lower water levels under ALT-C. Occasionally the southern end of WCA-3A experiences an area of decreased water depths under ALT-C relative to F2050, which is contiguous with the decreased water depths ALT-C predicts for East Slough. Additionally there is a small region of increased water under ALT-C relative to F2050 along the border between the East and West Panhandle areas.

D-C.2.6.2 ATLSS High Resolution Hydrology Output Comparison

The 1985-1994 10-year average rain fall hydroperiod analysis (Figure FCHYHPM1.PDF) shows increased hydroperiods under ALT-C relative to F2050 over most of the study area. This area is contiguous and covers WCA-1, WCA-2A, most of WCA-2B, most of WCA-3A south of I-75, WCA-3B, Shark River Slough, North Taylor Slough, and the north eastern portion of BCNP. An additional disjoint region which experiences increased hydroperiod under ALT-C relative to F2050 appears along the border between the East and West Panhandle. Along the southern end of WCA-3A ALT-C and F2050 predict a region of equal hydroperiod which is connected to the region of equal or shortened ALT-C hydroperiod in the

East Slough. In the 10-Mile Marl area, the southern end of East Slough, the north east corner of WCA-3A, the eastern most edge of WCA-2B and a small region in the West Panhandle ALT-C predicts shorter hydroperiods relative to F2050. The area of ALT-C shortened hydroperiod in the East Slough area is surrounded by a region for which ALT-C and F2050 predict equivalent hydroperiods. The largest decrease in hydroperiods predicted by ALT-C relative to F2050 occurs in the north east corner of WCA-3A and in WCA-2B. For most of the central and western portions of BCNP, most of the Long Pine Key area, and South Taylor Slough there are negligible differences between the hydroperiods predicted by ALT-C and F2050. The basic pattern of long and short hydroperiod predicted by ALT-C relative to F2050 under the 10-year average rain fall condition are present during the other rain fall conditions. During the average of the five lowest rain fall conditions (Figure FCHYHPM2.PDF) ALT-C predicts almost no change in the amount of area for which ALT-C predicts increased water depth relative to F2050, but the differences between the two scenarios becomes larger than those seen under the 10-year average rain fall conditions. For the lowest rain fall conditions, 1990, (Figure FCHYHPM3.PDF) there is a decrease in the amount of area for which ALT-C predicts longer hydroperiods relative to F2050. Regions including the center of WCA-2A, the southern end of WCA-3A, northern end of Shark River Slough, South Taylor Slough and Long Pine Key are give equivalent hydroperiods under ALT-C and F2050. The region of shortened hydroperiod in the 10-Mile Marl area and southern East Slough predicted by ALT-C relative to F2050 is diminished in both spatial extent and peak value during the lowest rain fall year, 1990, (Figure FCHYHPM3.PDF). In the north east corner of WCA-3A, the eastern most part of WCA-2B and the area in the West Panhandle ALT-C predicts shorter hydroperiods relative to F2050 under the lowest rain fall conditions (Figures FCHYHPM2.PDF and FCHYHPM3.PDF). During the year of lowest rain fall, 1990, (Figure FCHYHPM3.PDF) the difference in hydroperiods between the two scenarios becomes larger in the north east corner of WCA-3A and in the West Panhandle. The region of decreased hydroperiod in east WCA-2B which appears under other rain fall conditions is not present under the lowest rain fall conditions. Under the lowest rain fall conditions an area along the L-67 levees is given shorter hydroperiods under ALT-C relative to F2050. Under the highest rain fall conditions (Figure FCHYHPM4.PDF and FCHYHPM5.PDF) the region for which ALT-C predicts increased hydroperiod relative to F2050 under the 10-year average is decreased both in spatial extent and peak value. Under the high rain fall conditions portions of WCA-1, most of WCA-2A and Shark River Slough are given comparable hydroperiods by both ALT-C and F2050. Under the highest rain fall year, 1969, (Figure FCHYHPM5.PDF) most of the area within WCA-3A north of I-75, the north east end of Shark River Slough, and a corner of WCA-3B are all given equivalent hydroperiods by both ALT-C and F2050. An area for which ALT-C predicts lower hydroperiod relative to F2050 persists in the center of WCA-3A north of I-75 under the highest rain fall conditions though it is smaller in spatial extent. The northern end of the 10-mile Marl area and East Slough are given shorter hydroperiods under

ALT-C relative to F2050 during the high rain fall conditions (Figures FCHYHPM4.PDF and FCHYHPM5.PDF). In the southern end of the 10-mile Marl area, a region which under other rain fall conditions is given shorter hydroperiod by ALT-C, is given a longer hydroperiod by ALT-C relative to F2050 during the highest rain fall conditions. Under the high rain fall conditions (Figures FCHYHPM4.PDF and FCHYHPM5.PDF) the region of long hydroperiod predicted by ALT-C relative to F2050 along the border between the West and East Panhandle shows smaller difference between the two scenarios. During the average rain fall conditions, 1977, (Figure FCHYHPM6.PDF) most of the study area, including WCA-1, WCA-3A south of I-75, WCA-3B, Shark River Slough, North Taylor Slough, the eastern part of BCNP and the border between the West and East Panhandle area are given a longer hydroperiod by ALT-C relative to F2050 with lower predicted hydroperiods in a large portion of WCA-3A north of I-75, the southern end of the 10-Mile Marl area and East Slough. Most of WCA-2A is given equal or shorter hydroperiods by ALT-C relative to F2050 under the average rain fall conditions with a small region of increased hydroperiod along the north east border shared with WCA-1. An additional area in the south east portion of BCNP is given longer hydroperiods under ALT-C relative to F2050 only during the average rain fall conditions. As in the other years, during the average rain fall year ALT-C and F2050 predicts similar hydroperiods for Long Pine Key, South Taylor Slough, and central and western BCNP. Overall the pattern of differences between ALT-C and F2050 are consistent during all rain fall conditions. Much of the study area is given a longer hydroperiod under ALT-C as compared to F2050 and only the areas in WCA-3A north of I-75, the 10-Mile Marl area, East Slough, and the eastern most portion of WCA-2B have shorter hydroperiods under ALT-C relative to F2050. A few areas including the South Taylor Slough, part of the West Panhandle and central to western BCNP experience equivalent hydroperiods under both ALT-C and F2050. The general pattern of hydroperiods predicted by ALT-C are very similar to those predicted by ALT-D. The only major differences appear in the Dwarf Cypress/Lostmans Pine area. Within this region ALT-D predicts longer hydroperiod relative to F2050 while ALT-C predicts hydroperiods similar to those predicted by F2050.

D-C.2.7 Alternative D vs. F2050 (Revised)

D-C.2.7.1 SFWMM Output Comparisons

In the raw output from the SFWMM for the ALT-D and F2050 scenarios the differences in water depth show clear and stable patterns. ALT-D generates increased water levels relative to F2050 in WCA-1, most of WCA-3A south of I-75, WCA-3B, and most of the Evergaldes National Park (ENP) including Shark River Slough, Taylor Slough, Long Pine Key, and the East and West Panhandle areas. ALT-D predicts lower water levels in parts of the Rotenberger-Holeyland area, a portion of WCA-3A north of I-75, most of the southern end of WCA-2A, WCA-2B, East Slough and a small region south of East and West Panhandle areas. In Big Cypress National Preserve (BCNP) the differences between ALT-D and F2050 show only nominal differences is water depth between the two scenarios. For most of BCNP ALT-D predicts deeper water with scattered areas of decreased water depth relative to F2050. These differences in BCNP do not form a consistent pattern of wetting or drying over the 31-year time frame. These patterns of increased and decreased water depth within the study area are consistent across the entire 1965-1995 time period with some year to year variation. In almost all years simulated by the SFWMM ALT-D predicts lower water depths relative to F2050 in a contiguous region which includes the eastern half of the Rotenberger-Holeyland area, a band in WCA-3A north of I-75, the southern end of WCA-2A and WCA-2B. During all years the largest decrease in water depths between ALT-D and F2050 occur in the Rotenberger-Holeyland area and WCA-2B. The band of decreased water depths predicted by ALT-D relative to F2050 in WCA-3A north of I-75, which extends from the north east corner of WCA-3A south west into the conservation area, is present in almost every year. In some years, such as 1970, the band disappears and ALT-D predicts increased water depths relative to F2050 for most of WCA-3A north of I-75. In other years the spatial extent of the band increases and ALT-D predicts deeper water relative to F2050 for most of WCA-3A north of I-75. Relative to F2050, ALT-D predicts lower water depths in the eastern half of the Rotenberger-Holeyland area and higher water depths in the western half for almost all of the 31 year time period. For several of these years ALT-D predicts lower water depths for all of the Rotenberger-Holeyland area and for two years, 1983 and 1984, ALT-D predicts high water depths relative to F2050 for most of the area. In most years ALT-D predicts lower water levels in the southern part of WCA-2A and higher water levels in the northern part. Though the pattern within WCA-2A is present in almost every year, there are large variations in the extent of increased and decreased water depths produced by ALT-D relative to F2050. During some years, such as 1983, nearly all of WCA-2A has decreased water depths under ALT-D relative to F2050; while in 1988 ALT-D predicts higher water depths for the entire area. The increased water levels predicted by ALT-D relative to F2050 for WCA-3A south of I-75, WCA-3B, and the ENP are present over all 31 years. Over this time period the largest area of increase under ALT-D occur along Shark River Slough and in the eastern portion of WCA-3A parallel to the L-67 levies. Additionally there is a small region of increased water under ALT-D relative to F2050 along the border between the East and West Panhandle areas. Occasionally the southern end of WCA-3A experiences an area of decreased water depths under ALT-D relative to F2050 which is contiguous with the decreased water depths ALT-D predicts for East Slough.

D-C.2.7.2 ATLSS High Resolution Hydrology Output Comparison

The 1985-1994 10-year average rain fall hydroperiod analysis (Figure FDHYHPM1.PDF) shows increased hydroperiods under ALT-D relative to F2050 over most of the study area. This area is contiguous and covers WCA-1, WCA-2A, most of WCA-2B, most of WCA-3A south of I-75, WCA-3B, Shark River Slough, Taylor Slough, Long Pine Key, and the eastern portion of BCNP. An additional disjoint region which experiences increased hydroperiod under ALT-D relative to F2050 appears along the border between the East and West Panhandle. Along the southern end of WCA-3A ALT-D and F2050 predict a region of equal hydroperiod which is connected to the region of equal or shortened ALT-D hydroperiod in the East Slough. In the East Slough area, the north east corner of WCA-3A, the eastern most edge of WCA-2B and a small region in the West Panhandle ALT-D predicts shortening in hydroperiod relative to F2050. The area of ALT-D shortened hydroperiod in the East Slough area is surrounded by a region for which ALT-D and F2050 predict equivalent hydroperiods. The largest decrease in hydroperiods predicted by ALT-D relative to F2050 occurs in the north east corner of WCA-3A and in WCA-2B. For most of the central and western portions of BCNP and a small swath at the southern end of the study area there are negligible differences between the hydroperiods predicted by ALT-D and F2050. The basic pattern of long and short hydroperiod predicted by ALT-D relative to F2050 under the 10-year average rain fall condition are present during the other rain fall conditions. During the average of the five lowest rain fall conditions (Figure FDHYHPM2.PDF) ALTD predicts almost no change in the amount of area for which ALT-D predicts increased water depth relative to F2050, but the differences between the two scenarios becomes larger than those seen under the 10- year average rain fall conditions. For the lowest rain fall conditions, 1990, (Figure FDHYHPM3.PDF) there is a decrease in the amount of area for which ALT-D predicts longer hydroperiods relative to F2050. Regions including the center of WCA-2A, the southern end of WCA-3A, northern end of Shark River Slough, South Taylor Slough and Long Pine Key are give equivalent hydroperiods under ALT-D and F2050. In East Slough, the north east corner of WCA-3A, the eastern most part of WCA-2B and the area in the West Panhandle ALT-D predicts shorter hydroperiods relative to F2050 under the lowest rain fall conditions (Figures FDHYHPM2.PDF and FDHYHPM3.PDF). During the lowest rain fall condition, 1990, (Figure FDHYHPM3.PDF) the difference in hydroperiods between the two scenarios becomes larger in the north east corner of WCA-3A and in the West Panhandle. Under the same rain fall conditions the differences between ALT-D and F2050 becomes smaller in East Slough both in peak value and spatial extent. The region of decreased hydroperiod in east WCA-2B which appears under other rain fall conditions is not present under the lowest rain fall conditions. Under the lowest rain fall conditions a area along the L-67 levies is given shorter hydroperiods under ALT-D relative to F2050. Under the highest rain fall conditions (Figure FDHYHPM4.PDF and FDHYHPM5.PDF) the region for which ALT-D predicts increased hydroperiod relative to F2050 under the 10-year average is decreased both in spatial extent and peak value. Under these rain fall conditions most of WCA-2A, Shark River Slough, South Taylor Slough are given comparable hydroperiods by both ALT-D and F2050. Under the highest rain fall year, 1969, (Figure FDHYHPM5.PDF) most of the area within WCA-3A north of I-75, the north east end of Shark River Slough, and a corner of WCA-3B are all given equivalent hydroperiods by both ALT-D and F2050. The areas which ALT-D predicts as having shorter hydroperiod relative to F2050 under the 10-year average do not change greatly under the highest rain fall conditions. East Slough is still predicted as having a shorter hydroperiod under ALT-D relative to F2050, thought the differences in predicted hydroperiod becomes larger especially under the highest rain fall conditions, 1969, (Figure FDHYHPM5.PDF). The area in WCA-3A north of I-75 for which ALT-D predicts shorter hydroperiods relative to F2050 becomes smaller under the highest rain fall conditions but also experiences an increase in the difference between the predicted hydroperiods. Under the high rain fall conditions (Figures FDHYHPM4.PDF and FDHYHPM5.PDF) the region of long hydroperiod predicted by ALT-D relative to F2050 along the border between the West and East Panhandle shows a smaller difference between the two scenarios. There is a similar pattern of increased and decreased hydroperiod between ALT-D and F2050 under average rain fall conditions, 1977, (Figure FDHYHPM6.PDF) as is seen under the other rain fall conditions. WCA-1, WCA-3A south of I-75, WCA-3B, Shark River Slough, Taylor Slough, eastern BCNP and the border between East and West Panhandle are all given longer hydroperiods by ALT-D relative to F2050 under average rain fall conditions. The area in the north east corner of WCA-3A and the eastern most part of WCA-2B are still given shorter hydroperiod by ALT-D relative to F2050 under the average rain fall conditions. Along the northern border WCA-2A shares with WCA-1 there is a small region for which ALT-D predicts a longer hydroperiod than F2050 under average rain fall conditions. Over the remaining portion of WCA-2A ALT-D predicted hydroperiod equal to or shorter than those predicted by F2050. Under average rain fall conditions portions of the area of ALT-D shortened hydroperiod in East Slough is replaced by hydroperiods of similar length for both ALT-D and F2050. Immediately to the south in the 10-mile Marl area ALT-D predicts shorter hydroperiod than F2050.

Overall the pattern of differences between ALT-D and F2050 are consistent during all rain fall conditions. Much of the study area is given a longer hydroperiod under ALT-D as compared to F2050 and only the areas in WCA-3A north of I-75, East Slough, and the eastern most portion of WCA-2B have shorter hydroperiods under ALT-D relative to F2050. A few areas including the South Taylor Slough, part of the West Panhandle and central to western BCNP experience equivalent hydroperiods under both ALT-D and F2050.

D-C.3 ATLSS LANDSCAPE FISH MODEL

ATLSS
Landscape Fish Model (ALFISH)
Brief Description
November 1997

Donald DeAngelis, Holly Gaff, Louis Gross, Moris Shorrosh
The Institute for Environmental Modeling
University of Tennessee - Knoxville

The ATLSS Landscape Fish model (ALFISH) has as its main objective the ability to compare in a spatially-explicit manner the relative effects of alternative hydrologic scenarios on fresh-water fish densities across South Florida. Another objective is to provide a measure of the dynamic, spatially-explicit food resources available to wading birds.

ALFISH operates by splitting the landscape into spatial grid cells, of size 500 m by 500 m, characterizing the within-cell variability in water depth in a statistical manner. Within each cell, there is a distribution of elevations based upon an average hypsograph obtained by averaging data from a number of locations. Cells also contain permanently wet areas of small size, called ponds, with the remaining cell areas which may be subject to periodic dry down and reflooding called the marsh areas. Fish densities change within cells between areas of various depths as a cell drys down or rewets, since differing fractions of area within cells will be at differing water depths. The spatial cells are coupled in the model by movements of fish density between cells due to differences in relative fish densities or differences in relative water depth between cells. ALFISH is a mostly deterministic model, with the only stochastic component being the size of the pond within each cell.

The main inputs to ALFISH are hydrology data at a 500 m resolution from the pseudotopography model, time of year, and food resources available from lower trophic levels. For the current application of ALFISH to the Restudy, all lower trophic level resources are assumed constant, independent of hydrology. The time step of the model is 5-days, so hydrology data is averaged to produce 5-day average water depths for each 500 m cell across the study area. The study area includes all of the region for which hydrology data are being produced for each scenario, with some outputs being computed only for particular sub-regions within the study area.

ALFISH considers two fish functional groups: Functional Group #1 (small fish) includes all fish species which have a maximum possible length in the system of 7 cm; Functional Group #2 (large fish) includes all fish species with maximum lengths of greater than 7 cm. For example, the model would consider Killifishes or small live-bearers (Poeciliids) to be in functional group #1, while Gar and catfish would be in functional group #2. ALFISH treats the fish functional groups as an age-size structured model. Each age class is 30 days. The Large Fish functional group has 40 age classes, while the Small Fish functional group has 25 age classes. The Large Fish functional group has two stages: the first stage includes the first few age classes when fish are small in size and can be preyed upon by the second stage of larger, older fish. Each age class is divided into 6 size classes with length (in cm) calculated as a function of age from a Von Bertalanffy equation.

The fish in each functional group grow in size every 5-day time step, and move to the next age class every 30 days. Mature fish of each functional group produce a number of viable offspring during their reproductive month. The age of maturity, the fecundity, and the months during the year in which each functional group reproduces are parameters, which can differ for each functional group. Currently, only the age of maturity and the fecundity are unique to each functional group. For both functional groups, it is assumed that they can reproduce at the first time step of every month. There are four causes of mortality in ALFISH: (i) Background mortality, or the natural mortality of an uncrowded population, which is dependent on fish age class, but is independent of population size; (ii) Density-dependent mortality from starvation; (iii) Loss due to predation from other functional groups; and (iv) Death due to dry down in which some fraction of fish density do not successfully reach deeper water as a cell drys.

Movement in ALFISH has two phases. First, within cell movement takes place allowing fish density to move between the pond and the marsh areas of various depths within a particular cell. Secondly, fish density can shift between the marsh areas of adjoining cells, based on differences between water depth and fish densities in these cells. When the fraction of a cell with standing water has dropped too low, it is assumed there is no longer movement of fish into or out of that cell.

While ALFISH is capable of producing very detailed comparisons of changes in fish densities and size structure between scenarios, the outputs being placed on the website (hppt//www.restudy.org/atlss/) for distribution are just a small fraction of what it produces. All of the outputs in this report concern just the Small Fish functional group. The ALFISH outputs for the Restudy posted to the website are:

(1) Maps of the Small Fish functional group total number density (# fish/ m^2) in the marsh areas within cells over the entire region modeled at a 500 m x 500 m cell resolution generated for a single day at two times (model time step dates nearest July 1 and October 15). These maps will be produced for three years over the course of the simulation: a high, average, and low rainfall year.

(2) Maps of the Small Fish functional group total number density (# fish/ m^2) in the marsh areas within cells of fish > 2cm length over the entire region modeled at a 500 m x 500 m cell resolution generated for a single day at three times during wading bird breeding season (January 1, February 15, and April 1) in cells with appropriate water depth for wading bird foraging (10 cm to 30 cm water depth). These maps will be produced for three years over the course of the simulation: a high, average, and low rainfall year.

(3) Maps of average Small Fish functional group total number density (# fish/ m^2) in the marsh areas within cells over the entire 31 year scenario for these dates, with the July 1 and October 15 maps including fish of all size classes, and the January 1, February 15, and April 1 maps including just fish densities for those size classes > 2cm. These maps are all for the entire region, not just portions with certain water depths.

(4) Time series showing the average number density of the Small Fish functional group, averaged over the entire region, with output every 2 model time steps (e.g. every 10 days). Separate time series for fish densities in marsh and in pond areas.

(5) Time series showing the average number density of the Small Fish functional group (# fish/ m^2), for fish between 2 and 7 cm length, associated with each of the wading bird breeding season maps in (2) above. Time step for these series is every 5 days over the breeding season from December 15 to May 15, with separate time series for each of the maps described in (2) and for the 31-year average map described in (3).

(6) Time series showing the average number density of the Small Fish functional group in two subregions of WCA 3A (a long-hydroperiod and a short hydroperiod subregion, derived based upon empirical observations by Joel Trexler), with output every 2 model time steps (e.g. every 10 days), for fish between 2 and 7 cm length.

(7) Time series of histograms of the size distribution of the Small Fish functional group in the marsh areas of the two subregions of WCA 3A described in (6), with output every model step (e.g. every 5 days).

(8) Tables summarizing the total fish number densities broken down by basin area and by year. The entries represent fish per meter squared averaged over the entire year.

Outputs associated with the ATLSS Landscape Fish Model (ALFISH)

In accordance with the ATLSS file naming conventions, each file name consists of the characters:

"F","E", or "_" => F = the Future Without Project Condition (2050 Base)
E = Existing Condition (C1995 Base)
_ = No Base condition, a run of a scenario only
"0-9, A-Z" or "_" => Scenario Identifier (e.g. 0 = Scenario 0)
_ = No Scenario, a run of Base case only
"FI" => the ATLSS Fish Model
"XXXX" => 4 character mnemonic
"."
"PDF" or "TXT" or "DOC" => PDF, tabular text or documentation

Note: For all output, fish means only those in the Small Fish Functional Group (Functional Group #1). In addition, "total fish" means all fish are counted in all water depths. "Fish available for wading birds" means only fish greater than 2 cm in length found in water between 10 and 30 cm deep are counted. "Fish over 2cm long in all water" is used for only for maps which average the model output over several years. The units for all three are numbers of fish per meter squared.

1. Maps

The map outputs used to characterize the results of the ATLSS Fish Model will consist of 20 map images in the PDF file format. Each map shows a "Set" of model results, comparing a Base case to a Scenario, following the conventions for ATLSS comparison of two model runs. Each map has 3 panels. The left panel is the alternative scenario. The right panel is the base scenario - typically the Future without Project Conditions Case. The middle panel is the difference between the two scenarios.

For each of five dates during a high, low and average rainfall year the images provide a spatial display of the density of fish available for wading birds or total fish available upon that day. October 15 and July 1 display the total fish available on the model date closest to these in that year. The outputs for the other dates display only the fish available for wading birds. In addition, there are maps for the five dates averaged over 31 years of the run. These averages are total fish for the October 15 and July 1 dates, and fish over 2cm long in all water depths for the other three dates.

The mnemonic characters are composed according to the convention:

"XX" = Last two digits of the year or "MY" for the Mean value of all years.

"XX" = D1, D2, D3, D4, D5 -> the date designator

Listing of ALFISH map files for 2050 Base compared to Alternative 0:

File Name	Type of Year Closest Model Time Step to Day
XXFI68D1.PDF	High Rainfall Oct.
15XXFI69D2.PDF	High Rainfall Jan.
1XXFI69D3.PDF	High Rainfall Feb.
15 XXFI69D4.PDF	High Rainfall Apr.
1XXFI69D5.PDF	High Rainfall Jul.
1XXFI76D1.PDF	Average Rainfall Oct.
15XXFI77D2.PDF	Average Rainfall Jan.
1XXFI77D3.PDF	Average Rainfall Feb.

1XXFIMYD5.PDF	Average of all Years Jul. 1

2. Time Series Charts

The time series charts associated with ALFISH consists of the following files:

File Name	Description
XXFIAVGD.PDF	The total fish density in marsh and pond every 10 days averaged across the entire area.
XXFIBRY1.PDF	The fish available for wading birds in 10-30cm water for Dec 15, 1968 through May 15, 1969.
XXFIBRY2.PDF	The fish available for wading birds in 10-30cm water for Dec 15, 1976 through May 15, 1977.

XXFIBRY3.PDF	The fish available for wading birds in 10-30cm water for Dec 15, 1989 through May 15, 1990.
XXFIAVGB.PDF	The fish longer than 2cm in all water depths averaged for every year for Dec 15 through May 15.
XXFILHAB.PDF	The total fish in a long hydroperiod subregion of WCA 3A across all years. The two subregions together cover all of WCA 3A, are fixed throughout all model runs, and are derived from empirical estimates by Joel Trexler
.XXFISHAB.PDF	The total fish in a short hydroperiod subregion of WCA 3A across all years. The two subregions together cover all of WCA 3A, are fixed throughout all model runs, and are derived from empirical estimates by Joel Trexler.

3. Histograms

The histograms associated with ATLSS Fish Model display the size distribution of fish within two subregions of WCA 3A corresponding to long and short hydroperiods based upon empirical estimates by Joel Trexler, and give the fish size structure dynamics corresponding to the total fish data in file shown in XXFILHAB.PDF. Each image displays the size structure dynamics for half the years of the run. The histograms consist of the following files:

File Name	Description
X_FIBLH1.PDF	A size histogram for fish in the long hydroperiod subregion in WCA 3A in the indicated base scenario and the first half of the years of the run.
X_FIBLH2.PDF	A size histogram for fish in the long hydroperiod subregion in WCA 3A in the indicated base scenario and the second half of the years of the run.
_XFIALH1.PDF	A size histogram for fish in the long hydroperiod subregion in WCA 3A in the indicated alternative scenario for the first half of the years of the run.
_XFIALH2.PDF	A size histogram for fish in a the long hydroperiod subregion in WCA 3A given the indicated alternative scenario for the second half of the years of the run.
X_FIBSH1.PDF	A size histogram for fish in the short hydroperiod subregion in WCA 3A in the indicated base scenario and the first half of the years of the run.
X_FIBSH2.PDF	A size histogram for fish in the short hydroperiod subregion in WCA 3A in the indicated base scenario and the second half of the years of the run.

_XFIASH1.PDF	A size histogram for fish in the short hydroperiod subregion in WCA 3A in the indicated alternative scenario for the first half of the years of the run.
_XFIASH2.PDF	A size histogram for fish in the short hydroperiod subregion in WCA 3A in the indicated alternative scenario for the second half of the years of the run.

4. Tables

The tables associated with the ATLSS fish model consist of the following files:

File Name	Description
F_FIBASE.TXT	Total fish listed by years and basin areas for the Future Without Project Condition scenario.
_XFIBASE.TXT	Total fish listed by years and basin areas for the indicated scenario.
FXFIDIFF.TXT	The difference of the total fish listed by years and basin areas between the Future Without Project Condition and the indicated scenario.

D-C.3.1 F2050 (Revised) vs. C1995 (Revised)

Assessment of the Effects of Proposed Water Regimes C1995 (Revised) vs. F2050 (Revised)on the Fish Prey Base for Wading Birds in South Florida: Output of the ATLSS Fish Model

Figure FEFIAVGD.PDF indicates the same temporal pattern for total fish abundance in both C1995 and F2050; however, the total abundance of fish in the marsh areas in C1995 is higher by a factor of on average 1.15 than in F2050. For fish in pond areas, there is no similar pattern of overall fish abundance difference across the entire region, and average differences between C1995 and F2050 are less than two percent.

Figures FEFIBRY1.PDF, FEFIBRY2.PDF, FEFIBRY3.PDF and FEFIAVGB.PDF show the time series for fish in marsh during the wading bird breeding season assumed to be available to wading birds (e.g. including fish greater than 2 cm in length in water depths between 10 and 30 cm). Except in the low rainfall year (1990), C1995 tends to produce lower fish abundances available to wading birds early in the breeding season relative to F2050, while the reverse pattern holds in the latter part of the breeding season. Thus, for the 31 year average, fish abundance across the marsh is approximately 10% higher late in the breeding season in C1995 relative to F2050. These differences are particularly exaggerated in the high (1969) and average (1977) rainfall years, though there is little difference in the early breeding season. In the low rainfall year (1990), there is a consistent pattern of higher fish abundances available to wading birds in C1995 with more than twice as high fish densities in C1995 after early February.

The pattern of higher fish abundance in C1995 illustrated by the time series results described above do not occur uniformly across the spatial region being modeled. Five figures (FEFIMYD1.PDF through FEFIMYD5.PDF) show the 31 year (1965-1995) average values of total fish densities spatially across the ATLSS model region. Values shown are means for individual days that span the entire seasonal cycle (Oct 15, Jan 1, Feb 15, April 1, and July 1). These results clearly indicate a consistent pattern across all time periods of higher fish densities in C1995 versus F2050 in WCA3B, WCA3A (South), WCA1, So BCNP (N 41), South BCNP (S 41), and along the boundary between Long Pine Key and the Eastern Panhandle. There are significantly lower predicted total fish densities for C1995 as compared to F2050 for East Slough, Shark Slough, North Taylor Slough, the northern part of WCA3A (North), and WCA2B. These differences reflect the different hydroperiods associated with C1995 and F2050 for these regions as illustrated in FEHYHPM1.PDF and the other hydroperiod comparisons.

The spatial dynamics that produce the long-term average results discussed above are illustrated by the seasonal cycle of total fish abundance during October and July and fish availability for wading birds (fish greater than 2 cm in length, in water depths between 10 and 30 cm) for the January through April breeding season. Maps here illustrate these spatial dynamics for a typical rainfall year (1977, figs. FEFI76D1.PDF through FEFI77D5.PDF), a high rainfall year (1969, figs. FEFI68D1.PDF through FEFI69D5.PDF) and a low rainfall year (1990, figs. FEFI89D1.PDF through FEFI90D5.PDF). These maps illustrate the major influence of water depth differences between C1995 and F2050 particularly in WCA3A (South), WCA3B, along the boundary between Long Pine Key and the Eastern Panhandle, and WCA1 in which C1995 has consistently deeper water. They also reflect the consistent pattern of less water for C1995 relative to F2050 in WCA2B, Shark Slough, North Taylor Slough, and the northern and northwest portions of WCA3A (North). Thus, in the typical rainfall year, C1995 has consistently higher fish abundances in WCA3A (South) and WCA3B for all dates with the exception that the fish availability for wading birds in January (and somewhat in February) does not differ in the WCA3A (South) between the scenarios since the predicted water depths are too high for wading bird foraging. The relative fish density differences between C1995 and F2050 throughout the rest of the study area varies considerably through the year. In a low rainfall year (1990), WCA3A (South) is significantly higher in the October and January maps for C1995 compared with F2050 with some additional differences in WCA1 and WCA2A. For most of the low rainfall year (1990) model output shows few if any differences between the two scenarios in predicted fish densities since the overall predicted densities are extremely low in both scenarios. The pattern for a high rainfall year

(1969) shows complex spatial changes throughout the year with C1995 producing generally higher total fish abundances than F2050 in WCA3A (South) and WCA3B in October. The only other pattern for this high rainfall year (1969) is the tendency for C1995 to produce lower fish densities along the northern portion of WCA3A (North). The pattern of fish availability to wading birds in 1969 shows a complex intermingling of relative positive and negative differences between C1995 and F2050 through much of the ATLSS model region. In the very central portion of Shark River Slough in October and April, C1995 produces somewhat lower fish abundances for wading birds than F2050. No consistent pattern is evident throughout the rest of the region during the wading bird breeding season for 1969.

Tables _EFIBASE.TXT, F_FIBASE.TXT and FEFIDIFF.TXT show a breakdown by subregion of total fish density averaged over each year for C1995, F2050 and the difference respectively. These indicate the general pattern of higher fish density for C1995 relative to F2050 in 4 of the modeled subregions as measured by the mean over all years. The largest differences in this mean occur in WCA3B, WCA3A (South), and WCA1 with magnitudes varying from 50% to 75% higher for C1995. C1995 average fish density is significantly lower than that predicted for F2050 in WCA3A (North) and Shark Slough. The magnitudes of these differences relative to F2050 are much smaller however than the positive differences in the other subregions. In some of the above however, the table comparisons average over significant spatial variations in fish densities within subregions, which is particularly evident in WCA3A (North) (figs. FEFIMYD1.PDF through FEFIMYD5.PDF) and in the year to year variations in FEFIDIFF.TXT also for WCA3A (North).

D-C.3.1.1 Conclusion

The ATLSS fish model predicts that C1995 water conditions will produce average fish abundances consistently higher than those that would be expected under the F2050 water conditions in average across the modeled region particularly WCA3B, WCA3A (South), WCA1. However, C1995 provides consistently lower fish densities in WCA2B, the northeastern portion of WCA3A (North), East Slough and Shark Slough compared to F2050. In addition to these major differences in abundance patterns in different regions, the spatial pattern of differences in abundance varies somewhat based upon rainfall conditions in the particular year. Temporal patterns of total fish abundance averaged across the entire model region are similar with higher abundances produced by C1995. This does not holds true for fish availability to wading birds when including only fish greater than 2 cm in length in areas of appropriate depths for wading bird foraging during the early portion of the breeding season.

D-C.3.2 Alternative A vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative A versus F2050 (Revised)on the Fish Prey Base for Wading Birds in South Florida: Output of the ATLSS Fish Model

Figure FAFIAVGD.PDF indicates the same temporal pattern for total fish abundance in both ALT-A and F2050, however the total abundance of fish in the marsh areas in ALT-A is higher by a factor of 1.2 than in F2050 except at the very beginning and very end of the 31 year run. This pattern of higher abundances of fish in ALT-A also occurs for fish abundance in the pond areas though the difference is typically less than two percent.

Figures FAFIBRY1.PDF, FAFIBRY2.PDF, FAFIBRY3.PDF and FAFIAVGB.PDF show the time series for fish in marsh during the wading bird breeding season assumed to be available to wading birds (e.g. including fish greater than 2 cm in length in water depths between 10 and 30 cm). The pattern shows consistently higher fish available in ALT-A with essentially similar patterns of abundance in ALT-A and F2050. As shown by figure FAFIAVGB.PDF there is a consistent trend towards increasing numbers of fish available to wading birds as the breeding season progresses for ALT-A over F2050. The differences reach over a factor of 2 higher in ALT-A through out the breeding season for the high rainfall year (1969) as well as in the average rainfall year (1977). In the low rainfall year (1990), the results indicate a decreasing trend in fish available to wading birds for both ALT-A and F2050; however, ALT-A shows approximately twice the fish density of F2050 in the first half of the breeding season while in the second half, ALT-A maintains fish densities above 0.1 compared with F2050 which approaches extremely low levels.

The pattern of higher fish abundance in ALT-A illustrated by the time series results described above do not occur uniformly across the spatial region being modeled. Five figures (FAFIMYD1.PDF through FAFIMYD5.PDF) show the 31 year (1965-1995) average values of total fish densities spatially across the ATLSS model region. Values shown are means for individual days that span the entire seasonal cycle (Oct 15, Jan 1, Feb 15, April 1, and July 1). These results clearly indicate a consistent pattern across all time periods of higher fish densities in ALT-A versus F2050 in WCA3B, East Shark River Slough, Central Shark Slough, WCA1, WCA2B and North Taylor Slough, as well as in the northwestern portions of WCA2A. There are significantly lower predicted total fish densities for ALT-A as compared to F2050 for East Slough and South Big Cypress (South of 41). These differences reflect the different hydroperiods associated with ALT-A and F2050 for these regions as illustrated in FAHYHPM1.PDF and the other hydroperiod comparisons.

The spatial dynamics that produce the long-term average results discussed above are illustrated by the seasonal cycle of total fish abundance during October and July and fish availability for wading birds (fish greater than 2 cm in length, in water depths between 10 and 30 cm) for the January through April breeding season. Maps here illustrate these spatial dynamics for an typical rainfall year (1977, figs. FAFI76D1.PDF through FAFI77D5.PDF), a high rainfall year (1969, figs. FAFI68D1.PDF through FAFI69D5.PDF) and a low rainfall year (1990, figs. FAFI89D1.PDF through FAFI90D5.PDF). In the typical rainfall year (1977), ALT-A has consistently higher fish abundances in WCA3B and all of Shark Slough in October, April and July. However, the fish availability for wading birds in January does not differ in the Central Shark Slough between the scenarios since the predicted water depths are too high for wading bird foraging, and in February, there is a complex spatially variable pattern of differences between F2050 and ALT-A of fish available to wading birds in the Central Shark Slough. In a low rainfall year (1990), there is a consistent pattern in which ALT-A has consistently higher fish abundances and availability to wading birds but only in selected areas, particularly in the northwestern portions of WCA2A and the area along the boundary between WCA3B and Northeast Shark Slough. The pattern for a high rainfall year (1969) shows complex spatial changes throughout the year. The pattern of fish availability to wading birds in the high rainfall year (1969) shows a complex intermingling of relative positive and negative differences between ALT-A and F2050 through much of the ATLSS model region. No consistent pattern is evident throughout the region during the seasonal cycle for the high rainfall year (1969).

Tables _AFIBASE.TXT, F_FIBASE.TXT and FAFIDIFF.TXT show a breakdown by subregion of total fish density averaged over each year for ALT-A, F2050 and the difference respectively. These indicate the general pattern of higher fish density for ALT-A relative to F2050 when averaged over the entire modeled region by approximately 20%. This difference is not uniform across all regions. ALT-A average fish density is significantly lower than that predicted for F2050 in East Slough and South Big Cypress (South of 41). ALT-A produces higher fish densities when compared with F2050 in WCA1, WCA2A, WCA2B, WCA3B, Northeast Shark Slough, and Shark Slough. In some of the above however, the table comparisons average over significant spatial variations in fish densities within subregions, which is particularly evident in WCA3A North (figs. FAFIMYD1.PDF through FAFIMYD5.PDF) and in the year to year variations in FAFIDIFF.TXT also for WCA3A North.

D-C.3.2.1 Conclusion

The ATLSS fish model predicts that ALT-A water conditions will produce average fish abundances consistently higher than those that would be expected under the F2050 water conditions in most of the modeled region particularly Shark

Slough, WCA3B, WCA1, WCA2A, WCA2B, and northeast Shark Slough. However, ALT-A provides consistently lower fish densities in East Slough and South Big Cypress (South of 41) compared to F2050. In addition to these major differences in abundance patterns in different regions, the spatial pattern of differences in abundance varies somewhat based upon rainfall conditions in the particular year. Temporal patterns of total fish abundance averaged across the entire model region are similar with higher abundances produced by ALT-A. This holds true for both total abundance and fish availability to wading birds when including only fish greater than 2 cm in length in areas of appropriate depths for wading bird foraging.

D-C.3.3 Alternative B vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes ALTB vs. F2050 (Revised) on the Fish Prey Base for Wading Birds in South Florida: Output of the ATLSS Fish Model

Figure FBFIAVGD.PDF indicates the same temporal pattern for total fish abundance in both ALT-B and F2050, however the total abundance of fish in the marsh areas in ALT-B is consistently higher by a factor of 1.3 than in F2050. This pattern of consistently higher abundances of fish in ALT-B also occurs for fish abundance in the pond areas though the difference is typically less than two percent.

Figures FBFIBRY1.PDF, FBFIBRY2.PDF, FBFIBRY3.PDF and FBFIAVGB.PDF show the time series for fish in marsh during the wading bird breeding season assumed to be available to wading birds (e.g. including fish greater than 2 cm in length in water depths between 10 and 30 cm). The pattern shows consistently higher fish available in ALT-B with essentially similar patterns of abundance in ALT-B and F2050. As shown by figure FBFIAVGB.PDF there is a consistent trend towards increasing numbers of fish available to wading birds as the breeding season progresses for ALT-B over F2050. The differences reach over a factor of 2 higher in ALT-B late in the breeding season for the high rainfall year (1969) with ALT-B having a factor of 2.5 more fish in the average rainfall year (1977). In the low rainfall year (1990), the results indicate a decreasing trend in fish available to wading birds for both ALT-B and F2050; however, ALT-B shows approximately twice the fish density of F2050 in the first half of the breeding season while in the second half, ALT-B maintains fish densities above 0.2 compared with F2050 which approaches extremely low levels.

The pattern of higher fish abundance in ALT-B illustrated by the time series results described above do not occur uniformly across the spatial region being modeled. Five figures (FBFIMYD1.PDF through FBFIMYD5.PDF) show the 31 year (1965-1995) average values of total fish densities spatially across the ATLSS model region. Values shown are means for individual days that span the entire seasonal cycle (Oct 15, Jan 1, Feb 15, April 1, and July 1). These results clearly indicate a consistent pattern across all time periods of higher fish densities in ALT-B versus F2050 in WCA3B, East Shark River Slough, Central Shark Slough, WCA1, North Taylor Slough, Eastern Panhandle, as well as in the north western portions of WCA2A and WCA3A (South). There are significantly lower predicted total fish densities for ALT-B as compared to F2050 for WCA2B, the north eastern portion of WCA3A (North), the eastern boundary of WCA3A (South), East Slough and South Big Cypress (South of 41). These differences reflect the different hydroperiods associated with ALT-B and F2050 for these regions as illustrated in FBHYHPM1.PDF and the other hydroperiod comparisons.

The spatial dynamics that produce the long-term average results discussed above are illustrated by the seasonal cycle of total fish abundance during October and July and fish availability for wading birds (fish greater than 2 cm in length, in water depths between 10 and 30 cm) for the January through April breeding season. Maps here illustrate these spatial dynamics for an typical rainfall year (1977, figs. FBFI76D1.PDF through FBFI77D5.PDF), a high rainfall year (1969, figs. FBFI68D1.PDF through FBFI69D5.PDF) and a low rainfall year (1990, figs. FBFI89D1.PDF through FBFI90D5.PDF). In the typical rainfall year (1977), ALT-B has consistently higher fish abundances in Shark Slough in October, April and July. However, the fish availability for wading birds in January does not differ in the Central Shark Slough between the scenarios since the predicted water depths are too high for wading bird foraging, and in February, F2050 produces higher fish available to wading birds in the Central Shark Slough since the predicted water depths in ALT-B are still too high while those in F2050 are within the 10 to 30 cm restriction. In a low rainfall year (1990), there is a consistent pattern in which ALT-B has consistently higher fish abundances and availability to wading birds but only in selected areas, particularly in most of WCA1 and the northwestern portions of WCA2A and WCA3A (South). The pattern for a high rainfall year (1969) shows complex spatial changes throughout the year with ALT-B producing generally higher total fish abundances than F2050 in portions of western WCA3A and northeastern WCA3B in October and July. The pattern of fish availability to wading birds in the high rainfall year (1969) shows a complex intermingling of relative positive and negative differences between ALT-B and F2050 through much of the ATLSS model region. No consistent pattern is evident throughout the region during the wading bird breeding season for the high rainfall year (1969).

Tables _BFIBASE.TXT, F_FIBASE.TXT and FBFIDIFF.TXT show a breakdown by subregion of total fish density averaged over each year for ALT-B, F2050 and the difference respectively. These indicate the general pattern of higher fish density for ALT-B relative to F2050 when averaged over the entire modeled region by approximately 25%. This difference is not uniform across all regions. ALT-B average fish density is higher than that predicted for F2050 in most subregions except WCA2B, WCA3A (North), East Slough, South Big Cypress (North of 41) and South Big Cypress (South of 41). The largest positive differences in this mean occur in WCA1, WCA3A (South), WCA3B, Northeast Shark Slough, Shark Slough, and the Eastern Panhandle. In some of the above however, the table comparisons average over significant spatial variations in fish densities within subregions, which is particularly evident in WCA3A North (figs. FBFIMYD1.PDF through FBFIMYD5.PDF) and in the year to year variations in FBFIDIFF.TXT also for WCA3A North.

D-C.3.3.1 Conclusion

The ATLSS fish model predicts that ALT-B water conditions will produce average fish abundances consistently higher than those that would be expected under the F2050 water conditions in most of the modeled region particularly Shark Slough, WCA3B, WCA1, Eastern Panhandle and the northwestern portions of WCA3A South and WCA2A. However, ALT-B provides consistently lower fish densities in WCA2B, the northeastern corner of WCA3A North, East Slough, South Big Cypress (North of 41) and South Big Cypress (South of 41) compared to F2050. In addition to these major differences in abundance patterns in different regions, the spatial pattern of differences in abundance varies somewhat based upon rainfall conditions in the particular year. Temporal patterns of total fish abundance averaged across the entire model region are similar with higher abundances produced by ALT-B. This holds true for both total abundance and fish availability to wading birds when including only fish greater than 2 cm in length in areas of appropriate depths for wading bird foraging.

D-C.3.4 Alternative C vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes ALTC versus F2050 (Revised) on the Fish Prey Base for Wading Birds in South Florida: Output of the ATLSS Fish Model

Figure FCFIAVGD.PDF indicates the same temporal pattern for total fish abundance in both ALT-C and F2050, however the total abundance of fish in the marsh areas in ALT-C is consistently higher by a factor of on average 1.4 than in F2050. This pattern of consistently higher abundances of fish in ALT-C also occurs for fish abundance in the pond areas though the difference is typically less than two percent.

Figures FCFIBRY1.PDF, FCFIBRY2.PDF, FCFIBRY3.PDF and FCFIAVGB.PDF show the time series for fish in marsh during the wading bird breeding season assumed to be available to wading birds (e.g. including fish greater than 2 cm in length in water depths between 10 and 30 cm). The pattern shows consistently higher fish available in ALT-C with essentially similar patterns of abundance in ALT-C and F2050. As shown by figure FCFIAVGB.PDF there is a consistent trend towards increasing numbers of fish available to wading birds as the breeding season progresses for ALTC over F2050. However, at the end of the breeding season, ALT-C has a factor of 1.4 higher numbers of fish available to wading birds than F2050. The differences reach over a factor of 4 higher in ALT-C during some portions of the breeding season for the high rainfall year (1969) with ALT-C having a factor of 3 to 4 times more fish consistently across the average rainfall year (1977). In the low rainfall year (1990) ALT-C provides higher fish abundance to wading birds relative to F2050 by a factor of 3 to 40 with the largest magnitude differences occurring at the end of the breeding season. In the low rainfall year (1990), the results indicate a decreasing trend in fish available to wading birds for both ALT-C and F2050, with F2050 fish densities approaching extremely low levels while ALT-C densities level out at approximately 0.35 fish per meter squared. In the low rainfall year (1990), the within season variation in fish available to wading birds remains relatively consistent across the breeding season for ALT-C relative to that of F2050 which reaches extremely low levels of fish density by the middle of the breeding season.

The pattern of higher fish abundance in ALT-C illustrated by the time series results described above do not occur uniformly across the spatial region being modeled. Five figures (FCFIMYD1.PDF through FCFIMYD5.PDF) show the 31 year (1965-1995) average values of total fish densities spatially across the ATLSS model region. Values shown are means for individual days that span the entire seasonal cycle (Oct 15, Jan 1, Feb 15, April 1, and July 1). These results clearly indicate a consistent pattern across all time periods of higher fish densities in ALT-C versus F2050 in WCA3B, Northeast Shark River Slough, Central Shark Slough, WCA3A (South), WCA1, and the northwestern portion of WCA2A. There are significantly lower predicted total fish densities for ALT-C as compared to F2050 for the boundary between East Slough and South Big Cypress (South of 41), the northeast corner of WCA3A, and WCA2B. There are relatively minor higher fish densities in the Eastern Panhandle and Mullet Slough for ALT-C relative to F2050. These differences reflect the different hydroperiods associated with ALT-C and F2050 for these regions as illustrated in FCHYHPM1.PDF and the other hydroperiod comparisons.

The spatial dynamics that produce the long-term average results discussed above are illustrated by the seasonal cycle of total fish abundance during October and July and fish availability for wading birds (fish greater than 2 cm in length, in water depths between 10 and 30 cm) for the January through April breeding season. Maps here illustrate these spatial dynamics for a typical rainfall year (1977, figs. FCFI76D1.PDF through FCFI77D5.PDF), a high rainfall year (1969, figs. FCFI68D1.PDF through FCFI69D5.PDF) and a low rainfall year (1990, figs. FCFI89D1.PDF through FCFI90D5.PDF). In the typical rainfall year, ALT-C has higher fish abundances in Shark Slough and WCA3A (South) for October, April and July while in January the fish availability for wading birds does not differ in Shark Slough between the scenarios and in February ALT-C has lower fish available for wading birds in parts of these areas since the predicted water depths may be too high for wading bird foraging. In a low rainfall year (1990), ALT-C compared with F2050 has significantly higher fish abundances in the western region of WCA3A (South) in the October, January and February maps and the northwestern region of WCA2A as well as along the boundary between WCA3A (North) and WCA2B for all maps. The pattern for a high rainfall year (1969) shows complex spatial changes throughout the year with ALT-C producing generally higher total fish abundances than F2050 in portions of WCA3B, Shark Slough, Taylor Slough and WCA3A in October and July. The pattern of fish availability to wading birds in 1969 shows a complex intermingling of relative positive and negative differences between ALT-C and F2050 through much of the ATLSS model region. In the northwestern portion of WCA2A in October, January and February, ALT-C produces somewhat higher fish abundances for wading birds than F2050. No consistent pattern is evident throughout the rest of the region during the wading bird breeding season for 1969.

Tables _CFIBASE.TXT, F_FIBASE.TXT and FCFIDIFF.TXT show a breakdown by subregion of total fish density averaged over each year for ALT-C, F2050 and the difference respectively. These indicate the general pattern of higher fish density for ALT-C relative to F2050 in all but 4 of the modeled subregions as measured by the mean over all years. The largest differences in this mean occur in NE Shark Slough, WCA3B, WCA3A South, Shark Slough, Mullet Slough, WCA1 and WCA2A with magnitudes varying from 10% to 120% higher for ALT-C. ALT-C average fish density is lower than that predicted for F2050 in WCA2B, WCA3A (North) East Slough, and South Big Cypress (S 41). The magnitudes of these differences relative to F2050 are smaller however than the positive differences in the other subregions. In some of the above however, the table comparisons average over significant spatial variations in fish densities within subregions, which is particularly evident in WCA3A North (figs. FCFIMYD1.PDF through FCFIMYD5.PDF) and in the year to year variations in FCFIDIFF.TXT also for WCA3A North.

D-C.3.4.1 Conclusion

The ATLSS fish model predicts that ALT-C water conditions will produce average fish abundances consistently higher than those that would be expected under the F2050 water conditions in most of the modeled region particularly Shark Slough, WCA3B, WCA3A South, WCA1 and in WCA2A. However, ALT-C provides consistently lower fish densities in WCA2B, the northeastern corner of WCA3A North, East Slough and South Big Cypress (South of 41) compared to F2050. In addition to these major differences in abundance patterns in different regions, the spatial pattern of differences in abundance varies somewhat based upon rainfall conditions in the particular year. Temporal patterns of total fish abundance averaged across the entire model region are similar with higher abundances produced by ALT-C. This holds true for both total abundance and fish availability to wading birds when including only fish greater than 2 cm in length in areas of appropriate depths for wading bird foraging. Please note as well that the patterns of fish density produced by ALT-C are very similar to ALT-D although there are differences in the actual fish densities.

D-C.3.5 Alternative D vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative D versus F2050 (Revised) on the Fish Prey Base for Wading Birds in South Florida: Output of the ATLSS Fish Model

Figure FDFIAVGD.PDF indicates the same temporal pattern for total fish abundance in both ALT-D and F2050, however the total abundance of fish in the marsh areas in ALT-D is consistently higher by a factor of on average 1.5 than in F2050. This pattern of consistently higher abundances of fish in ALT-D also occurs for fish abundance in the pond areas though the difference is typically less than two percent.

Figures FDFIBRY1.PDF, FDFIBRY2.PDF, FDFIBRY3.PDF and FDFIAVGB.PDF show the time series for fish in marsh during the wading bird breeding season assumed to be available to wading birds (e.g. including fish greater than 2 cm in length in water depths between 10 and 30 cm). The pattern shows consistently higher fish available in ALT-D with essentially similar patterns of abundance in ALT-D and F2050. As shown by figure FDFIAVGB.PDF there is a consistent trend towards increasing numbers of fish available to wading birds as the breeding season progresses for ALT-D over F2050. However, at the end of the breeding season, ALT-D has a factor of 1.5 higher numbers of fish available to wading birds than F2050. The differences reach over a factor of 4 higher in ALT-D during some portions of the breeding season for the high rainfall year (1969) with ALT-D having a factor of 3 to 10 times more fish in the average rainfall year (1977) and the low rainfall year (1990). In the low rainfall year (1990), the results indicate a decreasing trend in fish available to wading birds for both ALT-D and F2050, with F2050 fish densities approaching extremely low levels while ALT-D densities level out at approximately 0.3 fish per meter squared. In the low rainfall year (1990), the within season variation in fish available to wading birds remains relatively consistent across the breeding season for ALT-D relative to that of F2050 which reaches extremely low levels of fish density by the middle of the breeding season.

The pattern of higher fish abundance in ALT-D illustrated by the time series results described above does not occur uniformly across the spatial region being modeled. Five figures (FDFIMYD1.PDF through FDFIMYD5.PDF) show the 31 year (1965-1995) average values of total fish densities spatially across the ATLSS model region. Values shown are means for individual days that span the entire seasonal cycle (Oct 15, Jan 1, Feb 15, April 1, and July 1). These results clearly indicate a consistent pattern across all time periods of higher fish densities in ALT-D versus F2050 in WCA3B, Northeast Shark River Slough, Central Shark Slough, WCA3A (South), WCA1, Mullet Slough, and the northwestern portion of WCA2A. There are significantly lower predicted total fish densities for ALT-D as compared to F2050 for the boundary between East Slough and South Big Cypress (South of 41), the northeast corner of WCA3A, and WCA2B. There are relatively minor higher fish densities in the Eastern Panhandle for ALT-D relative to F2050. These differences reflect the different hydroperiods associated with ALT-D and F2050 for these regions as illustrated in FDHYHPM1.PDF and the other hydroperiod comparisons.

The spatial dynamics that produce the long-term average results discussed above are illustrated by the seasonal cycle of total fish abundance during October and July and fish availability for wading birds (fish greater than 2 cm in length, in water depths between 10 and 30 cm) for the January through April breeding season. Maps here illustrate these spatial dynamics for a typical rainfall year (1977, figs. FDFI76D1.PDF through FDFI77D5.PDF), a high rainfall year (1969, figs. FDFI68D1.PDF through FDFI69D5.PDF) and a low rainfall year (1990, figs. FDFI89D1.PDF through FDFI90D5.PDF). In the typical rainfall year, ALT-D has consistently higher fish abundances in Shark Slough and WCA3A (South) for all dates with the exception that the fish availability for wading birds in January (and somewhat in February) does not differ in Shark Slough between the scenarios since the predicted water depths are too high for wading bird foraging. In a low rainfall year (1990), the western region of WCA3A (South) and the northwestern region of WCA2A are significantly higher in the October, January and February maps for ALT-D compared with F2050. The pattern for a high rainfall year (1969) shows complex spatial changes throughout the year with ALT-D producing generally higher total fish abundances than F2050 in WCA3B and portions of Shark Slough, Taylor Slough and WCA3A in October and July. In addition, ALT-D produces lower numbers of fish compared to F2050 throughout the year in the northeastern portion of WCA3A (North). The pattern of fish availability to wading birds in 1969 shows a complex intermingling of relative positive and negative differences between ALT-D and F2050 through much of the ATLSS model region. In the northwestern portion of WCA2A in October, January and February, ALT-D produces somewhat higher fish abundances for wading birds than F2050. No consistent pattern is evident throughout the rest of the region during the wading bird breeding season for 1969.

Tables _DFIBASE.TXT, F_FIBASE.TXT and FDFIDIFF.TXT show a breakdown by subregion of total fish density averaged over each year for ALT-D, F2050 and the difference respectively. These indicate the general pattern of higher fish density for ALT-D relative to F2050 in all but 4 of the modeled subregions as measured by the mean over all years. The largest differences in this mean occur in NE Shark Slough, WCA3B, WCA3A South, Shark Slough, Mullet Slough, WCA1 and WCA2A with magnitudes varying from 10% to 120% higher for ALT-D. ALT-D average fish density is lower than that predicted for F2050 in WCA2B, WCA3A (North) East Slough, and South Big Cypress (S 41). The magnitudes of these differences relative to F2050 are smaller however than the positive differences in the other subregions. In some of the above however, the table comparisons average over significant spatial variations in fish densities within subregions, which is particularly evident in WCA3A North (figs. FDFIMYD1.PDF through FDFIMYD5.PDF) and in the year to year variations in FDFIDIFF.TXT also for WCA3A North.

D-C.3.5.1 Conclusion

The ATLSS fish model predicts that ALT-D water conditions will produce average fish abundances consistently higher than those that would be expected under the F2050 water conditions in most of the modeled region particularly Shark Slough, WCA3B, WCA3A South, WCA1 and in WCA2A. However, ALT-D provides consistently lower fish densities in WCA2B, the northeastern corner of WCA3A North, East Slough and South Big Cypress (South of 41) compared to F2050. In addition to these major differences in abundance patterns in different regions, the spatial pattern of differences in abundance varies somewhat based upon rainfall conditions in the particular year. Temporal patterns of total fish abundance averaged across the entire model region are similar with higher abundances produced by ALT-D. This holds true for both total abundance and fish availability to wading birds when including only fish greater than 2 cm in length in areas of appropriate depths for wading bird foraging.

D-C.4 WADING BIRD BREEDING POTENTIAL INDEX

Wading Bird Foraging Conditions Index
Basic Model Description

Michael Huston, John Curnutt and Jane Comiskey
The Institute for Environmental Modeling
University of Tennessee
Knoxville, TN 37996-1610

D-C.4.1 Introduction

Through the 1960's, the Everglades served as a major breeding center for wading birds in the eastern United States. Over the past several decades, wading bird reproduction has declined dramatically, although the area is still an important feeding ground (Robertson and Frederick 1994). Numerous theories have been offered to explain the decline, including reduction in extent of habitat, reduced prey availability, alteration of drying rates, loss of peripheral short-hydroperiod wetlands, increase in frequency of drydowns, mercury toxicity, effects of eutrophication, shift in migratory patterns, and changes in storm frequency (summarized in Fleming, Wolff, and DeAngelis 1994).

Changing water management strategies for south Florida, which have coincided with decreases in colonial wading bird populations, affect many of the processes implicated in these declines. As part of the Central and Southern Florida Comprehensive Study Review (Restudy), the ecological impacts of a series of proposed alternative water management regimes will be evaluated. Each scenario will affect potential breeding activity of wading birds across the landscape.

The ATLSS Wading Bird Breeding Potential Index uses knowledge of how hydrologic factors affect the concentration and availability of food resources during the breeding season to compute a Breeding Potential Index (BPI) for wading birds. ATLSS expresses the effects of proposed scenarios as changes in the spatial pattern of breeding potential over the model area. The ATLSS sub-area reporting units are based on a combination of public area, drainage basin, and management unit subregion maps (see REPUNITS.PDF).

D-C.4.2 Methods

For most wading bird species, small freshwater fish and invertebrates are the primary food brought back to rookeries to feed young birds. Both the amount and timing of prey availability are critical to breeding success during any specific nesting season. SFWMM restoration scenario hydrology output is used to make spatially explicit estimates of surface area with water in the depth range needed for successful feeding for the group-foraging species (10-30 cm covers the range used by species such as ibis and wood storks).

The wading bird breeding cycle consists of courtship, nest-building/ breeding, incubation, feeding, and fledging. A breeding cycle is not initiated unless hydrologic conditions are appropriate. After nesting and feeding have been initiated, successful fledging will not occur unless adequate food is available over the period required for young to attain critical growth. The Breeding Potential Index focuses on food availability during the period from hatching to fledging, when young birds must be fed continuously. If the food supply is interrupted during this period, the young may starve, and most nesting efforts fail to produce fledglings. Such interruptions can occur if water levels fall too rapidly, stranding and killing the fish, or if water levels rise above the optimal depth range, which disperses the high concentrations of fish needed for efficient feeding. The critical feeding period ranges from 45 days for white ibises, snowy egrets, and small herons, to 80 days for wood storks (references in Frederick and Powell 1994, Bancroft et al. 1994).

ATLSS computes the daily average area of water in the optimal depth range (10-30 cm) over 3-day periods for subregions of the model area. If this average area in a subregion decreases by 30% or more from one averaging period to the next, the current nesting cycle is considered a failure, and calculations for a new nesting cycle are initiated. These calculations are made over the period from December 15 to May 15, which contains a maximum of 3 nesting cycles of 45 days each. The Breeding Potential Index is computed as the number of successful breeding cycles, scaled by the maximum potential number of breeding cycles. This calculation is performed for each subregion within the area covered by the SFWMM.

The Wading Bird BPI model is being run on SFWMM calibration/validation data for 1979--1995, and index values for subregions are being compared to reported densities for wading birds for those years (Bancroft et al. 1994, Cramer et al. 1997) to determine optimal settings for cycle length, subregion proportions, and temporal averaging period. A number of related indices and metrics, including cell by cell counts of successful cycles, relative distribution of ponding depth classes in the early dry season, drying rates, and productivity estimates, are initially being computed to aid in calibration and refinement of the model and in interpretation of index values.

The Wading Bird BPI is a composite index of spatial and temporal patterns. Spatial patterns will be computed based on ATLSS High Resolution Hydrology (28.5 x 28.5 meter units). This resolution captures the fine-scale spatial structure of the South Florida wetlands that creates the shallow depressions and ponding areas that are critical for wading bird feeding. However, because the index is based on a spatial average over landscape subregions, index values are reported for the larger spatial areas over which the mean is computed.

Output associated with the ATLSS Wading Bird Breeding Potential Index Model.

In accordance with ATLSS file naming conventions, each file name will consist of the characters:

"X" or "_" => the Base, typically F for the F2050 base or E for the C1995 base
"X" or "_" => the alternative scenario or base
"BD" => the ATLSS Wading Bird Breeding Potential Index Model
"XXXX" => 4 character mnemonic

"."
"PDF" or "TXT" or "DOC" => PDF, tabular text or documentation

ATLSS Wading Bird Breeding Potential Index

1. Maps

Map outputs used to characterize results of the Wading Bird component of the ATLSS Breeding Potential Index Model will consist of eight image files in PDF file format. Each map shows a "Set" of model results, comparing a Base case to a Scenario, following the conventions for ATLSS comparison of two model runs. Each map has 3 panels. The left panel is an alternative or base scenario. The right panel is the base scenario, typically the Future without Project Conditions Case. The middle panel is the difference between the two scenarios.

Each map depicts the model area at either a Fine (500-meter x 500-meter) or Coarse (2 mile) scale of resolution, with each cell color coded to represent either the value of the breeding potential index or the difference between the breeding potential index in the alternative or base scenario and the base scenario.

For each of a list of years, the images will provide a spatial display of breeding potential values during that year. In addition, there is an image file for the mean of all simulated years. The list of years includes years with high, low, and typical rainfall, and several years that serve to highlight the differences between the scenarios.

The mnemonic characters are composed according to the convention:

"XX" = Last two digits of the year

"XX" = CR - Coarse (2 mile) resolution, FR - Fine (500 meter) resolution

Listing of ATLSS Wading Bird Breeding Potential Index map files:

File Name	Time Period
XXBW69XX.PDF	A High Rainfall Year (1969)
XXBW70XX.PDF	Highlight Scenarios (1970)
XXBW77XX.PDF	A Typical Rainfall Year (1977)
XXBW83XX.PDF	Highlight Scenarios (1983)
XXBW90XX.PDF	A Low Rainfall Year (1990)
XXBW95XX.PDF	Highlight Scenarios (1995)
XXBWMYXX.PDF	Mean of All Years (1965->1995)

2. Time Series None

3. Histograms None

4. Tables

The tables associated with the ATLSS Wading Bird Breeding Potential Index Model will display the breeding indices by subregions and years. The tables will also be at either a 500 meter (FR = Fine Resolution) or 2 mile (CR = Coarse Resolution) scale as indicated by the file name.

File Name	Description
X_BWBAXX.TXT	Breeding index listed by subregions and years for the indicated base scenario.
_XBWALXX.TXT	Breeding index listed by subregions and years for the indicated alternative scenario.
XXBWDIXX.TXT	The difference of the breeding indices listed by subregions and years between the alternative and base scenarios.

D-C.4.3 F2050 (Revised) vs. C1995 (Revised)

Assessment of the Effects of Proposed Water Regimes F2050 (Revised) vs. C1995 (Revised) on Foraging Conditions for Wading Birds in South Florida

Because of differential spatial effects of proposed hydrologic modifications for south Florida, when we compare the results of two hydrological scenarios some regions of the model area will show changes favorable to wading bird foraging for a given year, while other regions for the same year will reflect a deterioration of conditions. The spatial and temporal dynamics of rookery formation involve the interplay of many factors and are not well understood; therefore, it is difficult to ascertain the effects of predicted foraging potentials on breeding activity. For example, suitable wading bird rookery sites are not distributed uniformly across the South Florida landscape, so a direct comparison of the magnitude of suitable foraging area available under alternative scenarios would be misleading. Therefore, we will interpret the current results the same way we have in the past, by limiting our discussion to areas where most birds have traditionally nested. Those areas are: (1) along the eastern part of WCA-3A, WCA-3B, and Northeast Shark River Slough (hereafter referred to as Northeastern Rookeries); and (2) the transition zone between Shark River Slough and the mangrove estuaries (hereafter referred to as the Southwestern Rookeries) (WBROOKS_.PDF).

D-C.4.3.1 Foraging Conditions Indices Results for Short-legged Wading Birds

Figure FEWSMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for short-legged wading birds across the model area. As indicated in the central panel of this set of three maps, C1995 produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FEWSMYFR.PDF) for most of WCA-2A, all of WCA2-B, most of WCA3-B, and most of the potential wading bird foraging habitat east of Shark Slough. For the areas including Northeastern rookeries (WCA-3A, WCA-3B, and Northeast Shark Slough), F-2050 results show slightly higher FCI's in the south while C1995 shows higher values for the north (including nearly all of WCA-3A). For the areas encompassing the Southwestern Rookeries, C1995 produces higher FCI values over most of the area relative to F2050, with the exception of the main Shark Slough drainage and lower Taylor Slough, where F2050 produces higher values.

The long-term average discussed above differs from predicted conditions during a "typical" year (1977, Fig. FEWS77FR.PDF), in that FCI values under the two scenarios are virtually the same across much of the area encompassing the Southwestern Rookeries, again with the exception of the main Shark River Slough drainage, where F2050 produces higher FCI's. In all other areas, the results for a typical year correspond with the 31-year mean.

During a high rainfall year (1969, Fig. FEWS69FR.PDF, which was not an exceptionally high water year), the F2050 scenario is superior to or equivalent to the C1995 scenario in terms of the wading bird feeding conditions throughout the area encompassing the Northeastern Rookeries (gray and blue colors in the central panel of Fig. FEWS69FR.PDF). This is especially pronounced in WCA-3A where foraging is precluded under C1995 while F2050 provides a range of FCI values. For the Southwestern Rookeries, Shark River Slough and southern Big Cypress produce higher FCI's under C1995 relative to F2050, while the East Slough shows higher values under F2050.

For 1983, a year of relatively high water, the pattern of FCI's are similar to those of 1969 (Fig. FEWS83FR.PDF). The higher water levels lead to a spatial constriction of potential foraging, including the loss of Shark River Slough as a foraging area under both scenarios. This leaves the area of the Southwestern Rookeries with higher FCI's under F2050 relative to C1995, although the extent of the areas that show a difference is negligible. For the Northeastern Rookeries, results of the two scenarios for 1983 are similar to those reported above for 1969, with a minor decrease in the spatial extent of potential foraging areas.

Under extremely high surface water conditions (1970 and 1995, Figs. FEWS70FR.PDF and FEWS70FR.PDF), foraging conditions are similar for both scenarios in the Water Conservation Areas and in northeast Shark Slough (i.e., unsuitable), but C1995 results in a higher FCI in small parts of the regions containing the Southwestern Rookeries and in North Taylor Slough, which may fall outside the range of the traditional foraging areas for the Northeastern Rookeries.

In the dry year of 1990 (Fig. FEWS90FR.PDF), F2050 and C1995 produce similar foraging conditions across the model area. FCI values are low for the Southwest Rookeries area and generally higher for the area encompassing the Northeastern Rookeries, where FCI values are slightly higher under C1995.

D-C.4.3.2 Foraging Conditions Indices Results for Long-legged Wading Birds

Figure FEWLMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for long-legged wading birds across the model area. As indicated in the central panel of this set of three maps, C1995 produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FEWLMYFR.PDF) for WCA1, WCA2-A, WCA2-B, WCA3-B and Northeast Shark River Slough. Conversely, F2050 results in a higher FCI for the greater part of WCA3-A. Thus, although one scenario does not result in higher FCI's for the entire area encompassing the Northeastern Rookeries, C1995 does so for the greater part of the area. For the areas encompassing the Southwestern Rookeries sites, F2050 produces slightly higher FCI,s throughout.

For a typical rainfall year (1977, Figure FEWL77FR.PDF) FCI results are similar across most of the model area under the two scenarios. The slight differences that do exist follow the same pattern as described above for the 31-year mean.

During a high rainfall year (1969, Fig. FEWL69FR.PDF, which was not an exceptionally high water year), the most significant differences between the scenarios are in WCA3-A (higher FCI's under F2050) and in southern WCA2-A (higher FCI's under C1995). Northeast Shark River Slough also shows higher FCI's under C1995. Thus, among the areas encompassing the Northeastern Rookeries, there is no clear advantage to either scenario in terms of FCI values. Much the same can be said for the area that includes the Southwestern Rookeries, although here F2050 produces slightly higher FCI's relative to C1995 in East Slough and southern Big Cypress.

For 1983, a relatively high water year, the primary difference between the two scenarios is the retention and consequent deeper water in WCA3-A under C1995 versus the lower WCA3-A water levels and consequent higher levels in

Shark River Slough (Fig. FEWL83FR.PDF). As with the results for 1969, the effects of these scenarios on the Northeastern Rookeries are mixed. For the Southwestern Rookeries, the predominant effect is higher FCI's in Shark River Slough under C1995.

Under high surface water conditions (1970, Fig. FEWL70FR.PDF), foraging conditions are unsuitable across the greater part of the area encompassing the Northeastern Rookeries under both F2050 and C1995. The differences that do exist between the scenarios are minor in extent and magnitude. Throughout the area encompassing the Southwestern Rookeries foraging conditions are suitable, except in the heart of Shark River Slough, under both scenarios. C1995 provides higher FCI's relative to F2050 over a restricted area near the Shark River Slough/mangrove interface. The same patterns are evident for 1995, an extremely high surface water year, except that foraging is even more restricted and under both scenarios the Shark River Slough/mangrove interface is unsuitable for foraging.

In the dry year of 1990 (Fig. FEWS90FR.PDF), long-legged wading bird foraging is restricted primarily to the WCA's and Shark River Slough under both F2050 and C1995. There is virtually no difference between the FCI's produced by the two scenarios in areas associated with the Southwestern Rookeries. Only slight differences occur in the Northeastern Rookeries area, and these can be attributed to higher FCI's under C1995.

D-C.4.3.3 Conclusion

For the area encompassing the Northeastern Rookeries, C1995 generally produces higher FCI's relative to F2050 under dry to "typical" conditions for both short-legged and long-legged wading birds. Under high rainfall and moderately high water conditions, F2050 produces higher FCI's relative to C1995 over parts of the area, most notably in WCA3-A. However, no one scenario dominates in higher FCI values. Under extreme high water conditions, neither scenario provides suitable foraging conditions over even a small fraction of the area.

For the area encompassing the Southwestern Rookeries, there is very little difference in the FCI values produced by C1995 and F2050 under dry conditions for both short-legged and long-legged wading birds. Under both scenarios, the extent of suitable foraging is restricted for long-legged wading birds. During "typical" and high rainfall, C1995 produces higher FCI values for short-legged birds, especially in Shark River Slough. Conversely, F2050 produces higher FCI values under these hydrologic conditions for long-legged wading birds. Under moderately high and high surface water conditions, C1995 produces higher FCI values relative to F2050 for both long- and short-legged wading birds. Under extremely high water conditions, short-legged wading bird foraging is significantly curtailed under both scenarios, but C1995 produces higher FCI values over a very small area. Long-legged birds, under these extremely high surface water conditions, do not experience the same magnitude of foraging area contraction. For these birds, there is virtually no difference between the FCI values produced under F2050 and C1995.

D-C.4.4 Alternative A vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative A versus F2050 (Revised) on Foraging Conditions for Wading Birds in South Florida

Because of differential spatial effects of proposed hydrologic modifications for south Florida, when we compare the results of an alternative scenario with those of the F2050 base scenario some regions of the model area will show changes favorable to wading bird foraging for a given year, while other regions for the same year will reflect a deterioration of conditions. The spatial and temporal dynamics of rookery formation involve the interplay of many factors and are not well understood; therefore, it is difficult to ascertain the effects of predicted foraging potentials on breeding activity. For example, suitable wading bird rookery sites are not distributed uniformly across the South Florida landscape, so a direct comparison of the magnitude of suitable foraging area available under alternative scenarios would be misleading. Therefore, we will interpret the current results the same way we did in the past, by limiting our discussion to areas where most birds have traditionally nested. Those areas are: (1) along the eastern part of WCA-3A, WCA-3B, and Northeast Shark River Slough and (hereafter referred to as Northeastern Rookeries); and (2) the transition zone between Shark River Slough and the mangrove estuaries (hereafter referred to as the Southwestern Rookeries) (WBROOKS_.PDF).

D-C.4.4.1 Foraging Conditions Indices Results for Short-legged Wading Birds

Figure FAWSMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for short-legged wading birds across the model area. As indicated in the central panel of this set of three maps, Alternative A produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FAWSMYFR.PDF) for the southern half of WCA-2A, eastern and northern WCA-3A, northern WCA-3B, and the prairies from Shark River Slough to the Eastern Panhandle. Alternative A produces significantly higher FCI values, relative to F2050, for far northern WCA-3B and a small area east of WCA-3A. For the area encompassing the Northeastern rookeries (WCA-3A, WCA-3B, and Northeast Shark Slough), F2050 results show slightly higher mean FCI's from middle WCA-3B south to Northeast Shark River Slough. For the areas encompassing the Southwestern Rookeries, F2050 produces higher FCI values over most of the area relative to Alternative A, with the above noted exception of the southern wetlands east of Shark River Slough, where Alternative A produces higher values.

The long-term average discussed above differs from predicted conditions during a "typical" year (1977, Fig. FAWS77FR.PDF), in that FCI values under the two scenarios are virtually the same across much of the area encompassing the Southwestern Rookeries. For the Northeastern Rookeries, Alternative A produces higher or equivalent FCI values over all but Northeast Shark Slough, including significantly higher values in northern WCA-3B and east of the WCA's.

In the dry year of 1990 (Fig. FAWS90FR.PDF), where differences exist between the two scenarios, Alternative A clearly produces higher or equivalent FCI values relative to F2050 in most cases, including the areas encompassing the Northeastern and Southwestern Rookeries.

During a high rainfall year (1969, Fig. FAWS69FR.PDF, which was not an exceptionally high water year), the F2050 scenario provides higher FCI values across most of the model area relative to Alternative A (gray and blue colors in the central panel of Fig. FAWS69FR.PDF). This is especially pronounced in most of WCA-3B, where foraging is precluded under Alternative A while F2050 provides a range of FCI values. For the Northeastern Rookeries the exceptions to the above are two small areas east of the WCA's, a strip of land in far northeastern WCA-3A south, and the northern tip of WCA-3B. For the Southwestern Rookeries, F2050 allows for foraging conditions across a greater extent of Shark River Slough relative to Alternative A, while Alternative A produces slightly higher FCI values relative to F2050 in and around southern Big Cypress. Otherwise, the two scenarios provide equivalent values in the area encompassing the Southwestern Rookeries.

For 1983, a year of relatively high water (Fig. FAWS83FR.PDF), there is a spatial constriction of potential foraging, including the loss of Shark River Slough and southern WCA-3A as a foraging area under both scenarios. The northern part of the Southwestern Rookeries experiences higher FCI values under Alternative A, relative to F2050, solely due to the effect on southern Big Cypress. Across the remaining area of the Southwestern Rookeries, the FCI values produced under the two scenarios are equivalent or slightly higher under F2050. For the Northeastern Rookeries, foraging is greatly reduced under these high water conditions. Alternative A provides low values for the eastern edge of WCA-3A, but in the remaining suitable foraging sites F2050 allows for higher FCI values.

Under extremely high surface water conditions (1970 and 1995, Figs. FAWS70FR.PDF and FAWS95FR.PDF), predicted foraging conditions are similar for both scenarios in the Water Conservation Areas and in northeast Shark Slough (i.e., unsuitable). For the Northeastern Rookeries, F2050 provides a greater spatial extent of suitable foraging relative to Alternative A, although even this advantage is so restricted as to be inconsequential. For the Southwestern Rookeries, F2050 provides higher FCI values in East Slough for the 1970 model year, while to the north Alternative A provides higher or equivalent values. In 1995, the wettest year of record, Alternative A produces higher or equivalent FCI values, relative to F2050, throughout the Southwestern Rookeries area.

D-C.4.4.2 Foraging Conditions Indices Results for Long-legged Wading Birds

Figure FAWLMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for long-legged wading birds across the model area. As indicated in the central panel of this set of three maps, Alternative A produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FAWLMYFR.PDF) for all regions except eastern WCA-3B, southern Big Cypress, Northeast Shark River Slough, the main drainage of Shark River Slough and the Eastern Panhandle. In these areas F2050 results in a higher FCI values. Thus, for the area encompassing the Northeastern Rookeries, Alternative A generally produces higher FCI values relative to F2050. For the areas encompassing the Southwestern Rookeries, neither scenario produces higher FCI values throughout.

For a "typical" rainfall year (1977, Fig. FAWL77FR.PDF), FCI values are similar for both scenarios across most of the model area. For the area encompassing the Northeastern Rookeries, Alternative A produces higher or equivalent values throughout, except for the northeast corner of Northeast Shark Slough and a scattering of sites in eastern WCA-3A. For the Southwestern Rookeries, there is virtually no difference between scenarios in terms of FCI values produced.

For a dry year, (1990 Fig. FAWL90FR.PDF) the spatial extent of suitable foraging conditions for long-legged wading birds is constricted under both scenarios. Alternative A, however, produces higher FCI values relative to F2050 at nearly every location for which a difference exists between the scenarios. Therefore, Alternative A is clearly more conducive to wading bird foraging in both rookery areas relative to F2050.

During a high rainfall year (1969, Fig. FAWL69FR.PDF, which was not an exceptionally high water year), the primary difference between the two scenarios lies in southern WCA-3B and Northeast Shark Slough. Here, suitable foraging conditions are precluded under Alternative A but not under F2050. Even though Alternative A does produce higher FCI values, relative to F2050, in northern WCA-3B and along the eastern edge of WCA-3A, the greater spatial extent of foraging under F2050 suggests that this scenario is more favorable to the Northeastern Rookeries. The same can be said for the Southwestern Rookeries, where Alternative A provides slightly higher FCI values, relative to Alternative A, only in south Big Cypress.

During a relatively high water year (1983, Fig. FAWL83FR.PDF), the main channel of Shark River Slough is unsuitable for long-legged wading bird foraging under both scenarios. The differences that exist between the scenarios are minor. For the Northeastern Rookeries, Alternative A produces higher FCI values, relative to F2050, over a slightly greater area. For the Southwestern Rookeries, F2050 produces slightly higher values. The limited extent of the differences between the two scenarios under these hydrologic conditions are minor in spatial extent and magnitude.

Under high surface water conditions (1970 and 1995, Figs. FAWL70FR.PDF and FAWL95FR.PDF), foraging conditions are unsuitable across the greater part of the area encompassing the Northeastern Rookeries under both F2050 and Alternative A. Alternative A, however, does produce higher FCI values, relative to F2050, except along the eastern edge of WCA-3B and southern Northeast Shark Slough. Throughout the area encompassing the Southwestern Rookeries, foraging conditions are suitable, except in the heart of Shark River Slough, under both scenarios. F2050 provides higher FCI's relative to Alternative A in the area of the Shark River Slough/mangrove interface.

D-C.4.4.3 Conclusion

For the area encompassing the Northeastern Rookeries, Alternative A generally produces higher FCI's relative to F2050 under dry to "typical" conditions for both short-legged and long-legged wading birds. With increasing water depth, F2050 produces higher FCI values over an increasing proportion of the area, first for short-legged wading birds and then for long-legged birds. However, no one scenario dominates in higher FCI values. Under extreme high water conditions, neither scenario provides suitable foraging conditions over even a small fraction of the area.

For the area encompassing the Southwestern Rookeries, Alternative A produces higher FCI values relative to F2050 under dry conditions for both short-legged and long-legged wading birds. Under both scenarios, the extent of suitable foraging is restricted for long-legged wading birds in the driest years. During "typical" and high rainfall years, the differences between the scenarios are minor. Under extremely high water conditions, short-legged wading bird foraging is significantly curtailed under both scenarios. Alternative A produces higher FCI values over a very small area and F2050 produces slightly higher values over a slightly greater area. Under extremely high surface water conditions, long-legged birds do not experience the same magnitude of foraging area contraction. For these birds, there is only a slight difference between FCI values produced under the two scenarios, with F2050 producing higher values relative to Alternative A.

D-C.4.5 Alternative B vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative B versus F2050 on Foraging Conditions for Wading Birds in South Florida

Because of differential spatial effects of proposed hydrologic modifications for south Florida, when we compare the results of an alternative scenario with those of the F2050 base scenario some regions of the model area will show changes favorable to wading bird foraging for a given year, while other regions for the same year will reflect a deterioration of conditions. The spatial and temporal dynamics of rookery formation involve the interplay of many factors and are not well understood; therefore, it is difficult to ascertain the effects of predicted foraging potentials on breeding activity. For example, suitable wading bird rookery sites are not distributed uniformly across the South Florida landscape, so a direct comparison of the magnitude of suitable foraging area available under alternative scenarios would be misleading. Therefore, we will interpret the current results the same way we did in the past, by limiting our discussion to areas where most birds have traditionally nested. Those areas are: (1) along the eastern part of WCA-3A, WCA-3B, and Northeast Shark River Slough and (hereafter referred to as Northeastern Rookeries); and (2) the transition zone between Shark River Slough and the mangrove estuaries (hereafter referred to as the Southwestern Rookeries) (WBROOKS_.PDF).

D-C.4.5.1 Foraging Conditions Indices Results for Short-legged Wading Birds

Figure FBWSMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for short-legged wading birds across the model area. As indicated in the central panel of this set of three maps, Alternative B produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FBWSMYFR.PDF) for most of WCA-2A, all of WCA-2B, northern and southern WCA-3A and most of the potential wading bird foraging habitat east of Shark Slough. Alternative B also produces higher FCI values east of WCA-3A and B. For the areas including Northeastern rookeries (WCA-3A, WCA-3B, and Northeast Shark Slough), F2050 results show slightly higher mean FCI's in WCA-3B and Northeast Shark River Slough, however, Alternative B shows higher values in potential foraging habitat east of the WCA's. For the areas encompassing the Southwestern Rookeries, F2050 produces higher FCI values over most of the area relative to Alternative B, with the above noted exception of the southern wetlands east of Shark River Slough, where Alternative B produces higher values.

The long-term average discussed above differs from predicted conditions during a "typical" year (1977, Fig. FBWS77FR.PDF), in that FCI values under the two scenarios are virtually the same across much of the area encompassing the

Southwestern Rookeries. For the Northeastern Rookeries, the same pattern can be seen in the "typical" year as described for the 31-year mean, however, differences between the two scenarios are more accentuated.

In the dry year of 1990 (Fig. FBWS90FR.PDF), foraging conditions are suitable across much of the landscape under both scenarios. Alternative B, however, produces higher or equivalent FCI values relative to F2050 throughout the areas encompassing the Northeastern and Southwestern Rookeries.

During a high rainfall year (1969, Fig. FBWS69FR.PDF, which was not an exceptionally high water year), the F2050 scenario provides higher FCI values across most of the model area relative to Alternative B (gray and blue colors in the central panel of Fig. FBWS69FR.PDF). This is especially pronounced in central WCA-3A and all of WCA-3B, where foraging is precluded under Alternative B while F2050 provides a range of FCI values. For the Northeastern Rookeries the exceptions to the above are two small areas east of the WCAs, a strip of land in far eastern WCA-3A, and the northern edge of WCA-2B. For the Southwestern Rookeries, F2050 allows for foraging conditions across a greater extent of Shark River Slough relative to Alternative B while Alternative B produces slightly higher FCI values relative to F2050 in and around East Slough. Otherwise, the two scenarios provide equivalent values in the area encompassing the Southwestern Rookeries.

For 1983, a year of relatively high water (Fig. FBWS83FR.PDF), there is a spatial constriction of potential foraging, including the loss of Shark River Slough as a foraging area under both scenarios. The northern part of the Southwestern Rookeries experiences higher FCI values under Alternative B, relative to F2050, solely due to the effect on East Slough. Across the remaining area of the Southwestern Rookeries the FCI values produced under the two scenarios are equivalent or slightly higher under F2050. For the Northeastern Rookeries, foraging is greatly reduced under these high water conditions. Alternative B provides low values for the eastern edge of WCA-3A, but in the remaining suitable foraging sites F2050 allows for higher FCI values.

Under extremely high surface water conditions (1970 and 1995, Figs. FBWS70FR.PDF and FBWS95FR.PDF) foraging conditions are similar for both scenarios in the Water Conservation Areas and in northeast Shark Slough (i.e., unsuitable). For the Northeastern Rookeries, F2050 provides a greater spatial extent of suitable foraging relative to Alternative D, although even this is so restricted as to be inconsequential. For the Southwestern Rookeries, F2050 provides slightly higher FCI values along the southern edge of the model area, while to the north Alternative B does so, especially in 1995, the wettest year of record.

D-C.4.5.2 Foraging Conditions Indices Results for Long-legged Wading Birds

Figure FBWLMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for long-legged wading birds across the model area. As indicated in the central panel of this set of three maps, Alternative B produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FBWLMYFR.PDF) for all regions except eastern WCA-3A, East Slough/ Big Cypress, and from WCA-3B through Northeast Shark River Slough and the main drainage of Shark River Slough. In these areas F2050 results in a higher FCI values. Thus, neither scenario results in higher FCI's for the entire area encompassing the Northeastern Rookeries. The same can be said for the areas encompassing the Southwestern Rookeries sites.

For dry and typical rainfall years (1990 and 1977, respectively, Figures FBWL90FR.PDF and FBWL77FR.PDF) Alternative B produces higher FCI values relative to F2050 except in Northeast Shark River Slough (only in typical rainfall year) and eastern WCA-3A (only in typical rainfall year), here F2050 produces higher FCI values. Under dry conditions, Alternative B produces higher or equivalent FCI values, relative to F2050, for both the Southwestern and Northeastern rookery areas. Under "typical' rainfall conditions, the differences between the two scenarios for the Southwestern Rookeries area is insignificant and for the Northeastern Rookeries both scenarios produce higher FCI values relative to one another for different parts of the area.

During a high rainfall year (1969, Fig. FBWL69FR.PDF, which was not an exceptionally high water year) and a relatively high water year (1983, Fig. FBWL83FR.PDF), F2050 provides higher FCI values relative to Alternative B in central WCA-3A, all of WCA-3B and Northeast Shark River Slough. Although Alternative B provides higher FCI values for a small area along the eastern edges of WCA-3A and B, the area encompassing the Northeastern Rookeries experiences overall higher FCI's under F2050. For the area that includes the Southwestern Rookeries, the two scenarios produce very similar results; where differences do exist, however, F2050 produces slightly higher FCI values relative to Alternative B across most of the area.

Under high surface water conditions (1970 and 1995, Figs. FBWL70FR.PDF and FBWL95FR.PDF), foraging conditions are unsuitable across the greater part of the area encompassing the Northeastern Rookeries under both F2050 and Alternative B. The differences that do exist between the scenarios are minor in extent. Throughout the area encompassing the Southwestern Rookeries, foraging conditions are suitable, except in the heart of Shark River Slough, under both scenarios. F2050 provides higher FCI's relative to Alternative B in the area of the Shark River Slough/mangrove interface.

D-C.4.5.3 Conclusion

For the area encompassing the Northeastern Rookeries, Alternative B generally produces higher FCI's relative to F2050 under dry to "typical" conditions for both short-legged and long-legged wading birds. Under high rainfall and moderately high water conditions, F2050 produces higher FCI's relative to Alternative B over parts of the area, most notably in WCA-3A. However, no one scenario dominates in higher FCI values. Under extreme high water conditions, neither scenario provides suitable foraging conditions over even a small fraction of the area.

For the area encompassing the Southwestern Rookeries, Alternative B produces higher FCI values relative to F2050 under dry conditions for both short-legged and long-legged wading birds. Under both scenarios, the extent of suitable foraging is restricted for long-legged wading birds in the driest years. During "typical" and high rainfall, the differences between the scenarios are less apparent than under drier conditions. Under extremely high water conditions, short-legged wading bird foraging is significantly curtailed under both scenarios. Alternative B produces higher FCI values over a very small area and F2050 produces slightly higher values over a slightly greater area. Under extremely high surface water conditions, long-legged birds do not experience the same magnitude of foraging area contraction. For these birds, there is only a slight difference between FCI values produced under the two scenarios, with F2050 producing higher values relative to Alternative B.

D-C.4.6 Alternative C vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative C versus F2050 (Revised) on Foraging Conditions for Wading Birds in South Florida

Because of differential spatial effects of proposed hydrologic modifications for south Florida, when we compare the results of an alternative scenario with those of the F2050 base scenario some regions of the model area will show changes favorable to wading bird foraging for a given year, while other regions for the same year will reflect a deterioration of conditions. The spatial and temporal dynamics of rookery formation involve the interplay of many factors and are not well understood; therefore, it is difficult to ascertain the effects of predicted foraging potentials on breeding activity. For example, suitable wading bird rookery sites are not distributed uniformly across the South Florida landscape, so a direct comparison of the magnitude of suitable foraging area available under alternative scenarios would be misleading. Therefore, we will interpret the current results the same way we did in the past, by limiting our discussion to areas where most birds have traditionally nested. Those areas are: (1) along the eastern part of WCA-3A, WCA-3B, and Northeast Shark River Slough and (hereafter referred to as Northeastern

Rookeries); and (2) the transition zone between Shark River Slough and the mangrove estuaries (hereafter referred to as the Southwestern Rookeries) (WBROOKS_.PDF).

D-C.4.6.1 Foraging Conditions Indices Results for Short-legged Wading Birds

Figure FCWSMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for short-legged wading birds across the model area. As indicated in the central panel of this set of three maps, Alternative C produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FCWSMYFR.PDF) for most of WCA-2A, all of WCA-2B, the northernmost portion of WCA-3A and most of the potential wading bird foraging habitat in and around Shark Slough. Alternative C also produces slightly higher FCI values throughout the Big Cypress National Preserve (BCNP). For the areas including Northeastern rookeries (WCA-3A, WCA-3B, and Northeast Shark Slough), F-2050 results show slightly higher mean FCI's across most of the area. However, Alternative C shows higher values in northern WCA-3B and in potential foraging habitat east of the WCA's. For the areas encompassing the Southwestern Rookeries, F2050 produces higher FCI values over most of the area relative to Alternative C, with the above noted exception of the Big Cypress and the southern wetlands east of Shark River Slough, where F2050 produces higher values.

The long-term average discussed above differs from predicted conditions during a "typical" year (1977, Fig. FCWS77FR.PDF), in that FCI values under the two scenarios are virtually the same across much of the area encompassing the Southwestern Rookeries. For the Northwestern Rookeries, the same pattern can be seen in the "typical" year as described for the 31-year mean, however, differences between the two scenarios are more accentuated.

In the dry year of 1990 (Fig. FCWS90FR.PDF), foraging conditions are suitable across nearly the entire landscape under both scenarios. Alternative C, however, produces higher or equivalent FCI values relative to F2050 throughout the areas encompassing the Northeastern and Southwestern Rookeries.

During a high rainfall year (1969, Fig. FCWS69FR.PDF, which was not an exceptionally high water year), the F2050 scenario is superior to or equivalent to the Alternative C scenario in terms of the wading bird feeding conditions throughout the area encompassing the Northeastern Rookeries (gray and blue colors in the central panel of Fig. FCWS69FR.PDF). This is especially pronounced in WCA-3A, where foraging is precluded under Alternative C while F2050 provides a range of FCI values. The only exceptions are two small areas east of the WCA's and the northern edge of WCA-2B. For the Southwestern Rookeries, F2050 allows for foraging conditions across a greater extent of Shark River Slough relative to

Alternative C while Alternative C produces slightly higher FCI values relative to F2050 over a small area of southern Big Cypress.

For 1983, a year of relatively high water (Fig. FCWS83FR.PDF), there is a spatial constriction of potential foraging, including the loss of Shark River Slough as a foraging area under both scenarios. This leaves the area of the Southwestern Rookeries with overall higher FCI's under Alternative C relative to F2050, although a slightly higher FCI is produced under F2050 just south of Shark River Slough. For the Northeastern Rookeries, F2050 allows foraging conditions over a greater area relative to Alternative C and, consequently, produces higher FCI values.

Under extremely high surface water conditions (1970 and 1995, Figs. FCWS70FR.PDF and FCWS95FR.PDF) foraging conditions are similar for both scenarios in the Water Conservation Areas and in northeast Shark Slough (i.e., unsuitable), but F2050 results in a higher FCI in East Slough near the Southwestern Rookeries in 1970, in 1995 this area is unsuitable for foraging under both scenarios. F2050 produces higher FCI values east of WCA-3A and B, within the area encompassing the Northeastern Rookeries.

D-C.4.6.2 Foraging Conditions Indices Results for Long-legged Wading Birds

Figure FCWLMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for long-legged wading birds across the model area. As indicated in the central panel of this set of three maps, Alternative C produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FCWLMYFR.PDF) for all regions except eastern WCA-3A, East Slough, and from southeastern WCA-3B through Northeast Shark River Slough and the main drainage of Shark River Slough. In these areas F2050 results in a higher FCI values. Thus, neither scenario results in higher FCI's for the entire area encompassing the Northeastern Rookeries. The same can be said for the areas encompassing the Southwestern Rookeries sites, except that F2050 produces slightly higher FCI's relative to Alternative C in East Slough.

For dry and typical rainfall years (1990 and 1977, respectively, Figures FCWL90FR.PDF and FCWL77FR.PDF) Alternative C produces higher FCI values relative to F2050 except in Northeast Shark River Slough (only in typical rainfall year) and a scattering of small areas in the northern third of the model area, here F2050 produces higher FCI values. Therefore, under these hydrologic conditions, Alternative C produces higher FCI values relative to F2050 for both the Northeastern and Southwestern Rookery areas.

During a high rainfall year (1969, Fig. FCWL69FR.PDF, which was not an exceptionally high water year) and a relatively high water year (1983, Fig.

FCWL83FR.PDF), F2050 provides higher FCI values relative to Alternative C in eastern WCA-3A, all of WCA-3B and Northeast Shark River Slough. Although Alternative C provides higher FCI values for a small area along the eastern edges of WCA-3A and B, the area encompassing the Northeastern Rookeries experiences overall higher FCI's under F2050. For the area that includes the Southwestern Rookeries, the two scenarios produce very similar results. However, F2050 produces slightly higher FCI values relative to Alternative C in Shark River Slough and southern Big Cypress, while East Slough shows slightly higher FCI values under Alternative C.

Under high surface water conditions (1970 and 1995, Figs. FCWL70FR.PDF and FCWL95FR.PDF), foraging conditions are unsuitable across the greater part of the area encompassing the Northeastern Rookeries under both F2050 and Alternative C. The differences that do exist between the scenarios are minor in extent. Throughout the area encompassing the Southwestern Rookeries, foraging conditions are suitable, except in the heart of Shark River Slough, under both scenarios. F2050 provides higher FCI's relative to Alternative C in the area of the Shark River Slough/mangrove interface.

D-C.4.6.3 Conclusion

For the area encompassing the Northeastern Rookeries, Alternative C generally produces higher FCI's relative to F2050 under dry to "typical" conditions for both short-legged and long-legged wading birds. Under high rainfall and moderately high water conditions, F2050 produces higher FCI's relative to Alternative C over parts of the area, most notably in WCA-3A. However, no one scenario dominates in higher FCI values. Under extreme high water conditions neither scenario provides suitable foraging conditions over even a small fraction of the area.

For the area encompassing the Southwestern Rookeries, Alternative C produces higher FCI values relative to F2050 under dry conditions for both short-legged and long-legged wading birds. Under both scenarios, the extent of suitable foraging is restricted for long-legged wading birds. During "typical" and high rainfall, Alternative C produces higher FCI values for short-legged birds and, to some extent, for long-legged wading birds as well. Under high and moderately high surface water conditions, Alternative C produces higher FCI values relative to F2050 for short-legged wading birds, while for long-legged birds there is little difference between the two scenarios. Under extremely high water conditions, short-legged wading bird foraging is significantly curtailed under both scenarios, but Alternative C produces higher FCI values over a very small area. Under these extremely high surface water conditions, long-legged birds do not experience the same magnitude of foraging area contraction. For these birds, there is only a slight difference between FCI values produced under the two scenarios, with F2050 producing higher values relative to Alternative C.

D-C.4.7 Alternative D vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative D versus F2050 (Revised) on Foraging Conditions for Wading Birds in South Florida

Because of differential spatial effects of proposed hydrologic modifications for south Florida, when we compare the results of an alternative scenario with those of the F2050 base scenario some regions of the model area will show changes favorable to wading bird foraging for a given year, while other regions for the same year will reflect a deterioration of conditions. The spatial and temporal dynamics of rookery formation involve the interplay of many factors and are not well understood; therefore, it is difficult to ascertain the effects of predicted foraging potentials on breeding activity. For example, suitable wading bird rookery sites are not distributed uniformly across the South Florida landscape, so a direct comparison of the magnitude of suitable foraging area available under alternative scenarios would be misleading. Therefore, we will interpret the current results the same way we did in the past, by limiting our discussion to areas where most birds have traditionally nested. Those areas are: (1) along the eastern part of WCA-3A, WCA-3B, and Northeast Shark River Slough and (hereafter referred to as Northeastern Rookeries); and (2) the transition zone between Shark River Slough and the mangrove estuaries (hereafter referred to as the Southwestern Rookeries) (WBROOKS_.PDF).

D-C.4.7.1 Foraging Conditions Indices Results for Short-legged Wading Birds

Figure FDWSMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for short-legged wading birds across the model area. As indicated in the central panel of this set of three maps, Alternative D produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FDWSMYFR.PDF) for most of WCA-2A, all of WCA2-B, the northernmost portion of WCA3-A and most of the potential wading bird foraging habitat east and west of Shark Slough. Alternative D also produces slightly higher FCI values throughout the Big Cypress National Preserve (BCNP). For the areas including Northeastern rookeries (WCA-3A, WCA-3B, and Northeast Shark Slough), F-2050 results show slightly higher mean FCI's across most of the area, however, Alternative D shows higher values in northern WCA3-B and in potential foraging habitat east of the WCA's. For the areas encompassing the Southwestern Rookeries, F2050 produces higher FCI values over most of the area relative to Alternative D, with the above noted exception of the Big Cypress and the southern wetlands east of Shark River Slough, where F2050 produces higher values.

The long-term average discussed above differs from predicted conditions during a "typical" year (1977, Fig. FDWS77FR.PDF), in that FCI values under the two scenarios are virtually the same across much of the area encompassing the Southwestern Rookeries. For the Northwestern Rookeries, the same pattern can be seen in the "typical" year as described for the 31-year mean, however, differences between the two scenarios are more accentuated.

In the dry year of 1990 (Fig. FDWS90FR.PDF), foraging conditions are suitable across nearly the entire landscape under both scenarios. Alternative D, however, produces higher or equivalent FCI values relative to F2050 throughout the areas encompassing the Northeastern and Southwestern Rookeries.

During a high rainfall year (1969, Fig. FDWS69FR.PDF, which was not an exceptionally high water year), the F2050 scenario is superior to or equivalent to the Alternative D scenario in terms of the wading bird feeding conditions throughout the area encompassing the Northeastern Rookeries (gray and blue colors in the central panel of Fig. FDWS69FR.PDF). This is especially pronounced in WCA-3A, where foraging is precluded under Alternative D while F2050 provides a range of FCI values. The only exceptions are two small areas east of the WCA's and the northern edge of WCA2-B. For the Southwestern Rookeries, F2050 allows for foraging conditions across a greater extent of Shark River Slough relative to Alternative D while Alternative D produces slightly higher FCI values relative to F2050 over a small area of southern Big Cypress.

For 1983, a year of relatively high water (Fig. FDWS83FR.PDF), there is a spatial constriction of potential foraging, including the loss of Shark River Slough as a foraging area under both scenarios. This leaves the area of the Southwestern Rookeries with overall higher FCI's under Alternative D relative to F2050, although a slightly higher FCI is produced under F2050 just south of Shark River Slough. For the Northeastern Rookeries, F2050 allows foraging conditions over a greater area relative to Alternative D and, consequently, produces higher FCI values.

Under extremely high surface water conditions (1970 and 1995, Figs. FDWS70FR.PDF and FDWS95FR.PDF) foraging conditions are similar for both scenarios in the Water Conservation Areas and in northeast Shark Slough (i.e., unsuitable), but Alternative D results in a higher FCI in East Slough near the Southwestern Rookeries. F2050 produces higher FCI values east of WCA3-A and B, within the area encompassing the Northeastern Rookeries.

D-C.4.7.2 Foraging Conditions Indices Results for Long-legged Wading Birds

Figure FDWLMYFR.PDF shows the 31 year (1965-1995) average values of Foraging Conditions Indices (FCI) for long-legged wading birds across the model area. As indicated in the central panel of this set of three maps, Alternative D produces average FCI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FDWLMYFR.PDF) for all regions except eastern WCA3-A, East Slough, and from southeastern WCA3-B through Northeast Shark River Slough and the main drainage of Shark River Slough. In these areas F2050 results in higher FCI values. Thus, although one scenario does not result in higher FCI's for the entire area encompassing the Northeastern Rookeries, Alternative D does so for the greater part of the area. The same can be said for the areas encompassing the Southwestern Rookeries sites, except that F2050 produces slightly higher FCI's relative to Alternative D in East Slough.

For dry and typical rainfall years (1990 and 1977, respectively, Figures FDWL90FR.PDF and FDWL77FR.PDF), FCI results are similar across much of the model area under the two scenarios. Where differences exist, Alternative D produces higher FCI values relative to F2050 except in Northeast Shark River Slough (only in typical rainfall year) and a scattering of small areas in the northern third of the model area, here F2050 produces higher FCI values.

During a high rainfall year (1969, Fig. FDWL69FR.PDF, which was not an exceptionally high water year) and a relatively high water year (1983, Fig. FDWL83FR.PDF), F2050 provides higher FCI values relative to Alternative D in eastern WCA3-A, all of WCA3-B and Northeast Shark River Slough. Although Alternative D provides higher FCI values for a small area along the eastern edges of WCA3-A and B, the area encompassing the Northeastern Rookeries experiences overall higher FCI's under F2050. For the area that includes the Southwestern Rookeries, F2050 produces slightly higher FCI's relative to Alternative D in Shark River Slough and southern Big Cypress, while East Slough shows slightly higher FCI values under Alternative D.

Under high surface water conditions (1970 and 1995, Figs. FDWL70FR.PDF and FDWL95FR.PDF), foraging conditions are unsuitable across the greater part of the area encompassing the Northeastern Rookeries under both F2050 and Alternative D. The differences that do exist between the scenarios are minor in extent and magnitude. Throughout the area encompassing the Southwestern Rookeries, foraging conditions are suitable, except in the heart of Shark River Slough, under both scenarios. F2050 provides higher FCI's relative to Alternative D in the area of the Shark River Slough/mangrove interface.

D-C.4.7.3 Conclusion

For the area encompassing the Northeastern Rookeries, Alternative D generally produces higher FCI's relative to F2050 under dry to "typical" conditions for both short-legged and long-legged wading birds. Under high rainfall and moderately high water conditions, F2050 produces higher FCI's relative to

Alternative D over parts of the area, most notably in WCA3-A. However, no one scenario dominates in higher FCI values. Under extreme high water conditions neither scenario provides suitable foraging conditions over even a small fraction of the area.

For the area encompassing the Southwestern Rookeries, Alternative D produces higher FCI values relative to F2050 under dry conditions for both short-legged and long-legged wading birds. Under both scenarios, the extent of suitable foraging is restricted for long-legged wading birds. During "typical" and high rainfall, Alternative D produces higher FCI values for short-legged birds and, to some extent, for long-legged wading birds as well. Under high and moderately high surface water conditions, Alternative D produces higher FCI values relative to F2050 for short-legged wading birds, while for long-legged birds there is little difference between the two scenarios. Under extremely high water conditions, short-legged wading bird foraging is significantly curtailed under both scenarios, but Alternative D produces higher FCI values over a very small area. Under these extremely high surface water conditions, long-legged birds do not experience the same magnitude of foraging area contraction. For these birds, there is only a slight difference between FCI values produced under the two scenarios, with F2050 producing higher values relative to Alternative D.

D-C.5 WHITE-TAILED DEER BREEDING POTENTIAL INDEX MODEL

White-tailed Deer Breeding Potential Index
Basic Model Description

Jane Comiskey and Louis Gross
The Institute for Environmental Modeling
University of Tennessee
Knoxville, TN 37996-1610

D-C.5.1 Introduction

The white-tailed deer is the largest herbivore in the Everglades and a major prey source for the endangered Florida panther. Since the early 1960's, when intensive water management began, the Everglades deer population has declined by almost 75%, from a high of 25-30,000 deer. Changing water management strategies for south Florida have impacted deer in several ways, affecting reproductive success and recruitment, movement and foraging, and forage production and availability (Fleming 1997). During wet years, extended periods of inundation with water depths over 2-ft. are common in the impounded marshes of the northern Everglades. During these high water events, deer move to elevated sites such as tree islands, where they often suffer deterioration of physical condition and increased susceptibility to parasites and disease as food stores became depleted. Does and fawns are particularly susceptible to the effects of prolonged high water.

As part of the Central and Southern Florida Comprehensive Study Review (Restudy), the ecological impacts of a series of proposed alternative water management regimes will be evaluated. Each of these scenarios will affect potential breeding and foraging activity of deer across the landscape. The ATLSS White-tailed Deer Breeding Potential Index (BPI) uses knowledge of how hydrologic factors affect the production and availability of food resources and the availability of dry bedding sites during the breeding season to compute a BPI for deer. ATLSS expresses the effects of proposed scenarios as changes in the spatial pattern of breeding potential over the model area. The ATLSS sub-area reporting units are based on a combination of public area, drainage basin, and management unit subregion Maps (see REPUNITS.PDF).

D-C.5.2 Methods

SFWMM restoration scenario hydrology output is used to make spatially explicit estimates of surface area with water in the depth ranges which restrict and preclude deer movement and fawning success.

The deer breeding cycle consists of mating, gestation, birth, lactation/nursing and fawn growth and maturation. Peak fawning occurs during the dry season (February -- March), when uninundated bedding sites are available. Fawns born in late winter to early spring will have grown enough to move about on the landscape when the wet season starts in May-June. The BPI focuses on the depth of ponded water, which would serve as an impediment to fawning, movement and foraging during the breeding season. If the food supply is interrupted during this period, the health of mother and offspring may suffer, and fawns are less likely to be recruited into the herd. Elevated water levels can make beds uninhabitable, and high water can drown young fawns.

For each landscape grid cell in the SFWMM model area, the model computes a daily feedback term, the ratio of the current ponding depth to a threshold depth above which deer movement and foraging is precluded. These daily feedback terms are summed over the time period from January 1 to May 31. The Breeding Potential Index is computed as 1 - ((feedback sum)/(days in summing period)). This results in an index between 0 and 1, with 0 representing no breeding potential, and 1 representing maximum potential (no interference from ponded water). This index is further scaled by a measure of habitat quality, using a metric of hydroperiod for each cell during the previous year as an indication of forage productivity and availability. Deer densities have been reported to be highest in areas with moderate hydroperiods (Fleming 1997.) Overdrained marshes with annual hydroperiods of less than 2-3 months do not support quality forage production, especially for females with young. When the ATLSS high-resolution forage model has been calibrated, the BPI Model will use forage estimates simulated for each grid cell rather than hydroperiod metrics.

The White-tailed Deer BPI model was initially run on SFWMM calibration/validation data for 1979-1995. Index values for subregions were compared to reported densities for deer in those years to determine optimal settings for water depth thresholds and habitat effects. A number of related indices and metrics, including yearly movement potential indices, are being computed to aid in scenario evaluation. Landscape grid cell index values will be represented pictorially as 3-panel difference maps, and spatial averages computed over landscape subregions will be reported in tabular form.

The Deer BPI is a composite index of spatial and temporal patterns. Spatial patterns will be computed based on ATLSS High Resolution Hydrology (28.5 x 28.5 meter units). This resolution captures fine-scale spatial heterogeneity of the South Florida wetlands and permits model representation of the elevated tree island habitats that are critical for deer survival during extended periods of high water.

Output associated with the ATLSS White-tailed Deer Breeding Potential Index Model.

In accordance with ATLSS file naming conventions, each file name will consist of the characters: UVXXYYZZ.EXT

"U" or "_" => the Base, typically F for the F2050 base or E for the C1995 base
"V" or "_" => the alternative scenario or base
"XX" => "BD" for the ATLSS White-tailed Deer BCI Model
"YYZZ" => 4 character mnemonic, described below
"."
"EXT" = "PDF" or "TXT" or "DOC" => PDF, tabular text or documentation

ATLSS White-tailed Deer Breeding Potential Index

1. Maps

Map outputs used to characterize results of the White-tailed Deer Breeding Potential Index Model will consist of eight image files in PDF file format. Each map shows a "Set" of model results, comparing a Base case to a Scenario, following the conventions for ATLSS comparison of two model runs. Each map has three panels. The left panel displays index values for an alternative or base scenario; the right panel displays index values for a base scenario, typically the Future without Project Conditions Case. The middle panel displays the cell-by-cell difference between index values for the two compared scenarios (e.g., ALT-A minus F2050).

Grid cells in the left and right panels are color-coded to represent the (positive) values of the displayed index, which range between 0 and 1. Cell colors in the center panel represent either positive (shades of gold) or negative (shades of blue) differences between index values displayed in the left panel and those in the right panel. Color keys are provided at the bottom of each map. Each map depicts the model area at either a Fine (500-meter x 500-meter) or Coarse (2-mile) scale of resolution.

For each of six selected years, images will provide a spatial display of index values for that year. In addition, an image file is provided for the mean of all simulated years. The selected years include years with high, low, and typical rainfall, and several additional years that serve to highlight differences between the compared scenarios.

The mnemonic characters are composed according to the convention:

"YY" = Last two digits of the year
"ZZ" = CR - Coarse (2 mile) resolution, FR - Fine (500 meter) resolution

Listing of ATLSS White-tailed Deer Breeding Potential Index map files:

File Name	Time Period
UVBD69ZZ.PDF	A High Rainfall Year (1969)
UVBD70ZZ.PDF	Highlight Scenarios (1970)
UVBD77ZZ.PDF	A Typical Rainfall Year (1977)
UVBD83ZZ.PDF	Highlight Scenarios (1983)
UVBD90ZZ.PDF	A Low Rainfall Year (1990)
UVBD95ZZ.PDF	Highlight Scenarios (1995)
UVBDMYZZ.PDF	Mean of All Years (1965->1995)

2. Time Series None.

3. Histograms None.

4. Tables

The tables associated with the ATLSS White-tailed Deer Breeding Potential Index Model will display the breeding indices by subregions and years. The tables will also be at either a 500 meter (FR = Fine Resolution) or 2 mile (CR = Coarse Resolution) scale as indicated by the file name.

File Name	Description
U_BDBASE.TXT	Breeding index listed by subregions and years for the indicated base scenario.
_VBDALTN.TXT	Breeding index listed by subregions and years for the indicated alternative scenario.
UVBDDIFF.TXT	The difference of the breeding indices listed by subregions and years between the alternative and base scenarios.

D-C.5.3 F2050 (Revised) vs. C1995 (Revised)

Assessment of the Effects of Proposed Water Regimes F2050 (Revised) vs. C1995 (Revised) on the Breeding Potential of White-tailed Deer in South Florida

Figure FEBDMYFR.PDF shows mean values over the 31 year simulation period (1965-1995) for the Breeding Potential Index (BPI) for white-tailed deer. As indicated in the central panel of this set of three maps, the C1995 hydrologic regime produces average BPI values which differ only slightly from those of F2050 throughout most of the modeled region, indicated by the gray, yellow and light blue colors, representing no difference or small positive or negative differences, respectively (see also Table FEBDDIFF.TXT, which lists mean BPI values for the various subregions delimited for evaluating ecological responses). The spatial pattern of these differences, however, is distinctive, and this pattern is consistent throughout the simulation period, with intensity and extent of differences varying with relative wetness of individual years. Higher BPI values are seen under C1995 in southern and western WCA-2A and WCA-2B, the Rotenberger and Holey Land WMA's, WCA-3A north of Alligator Alley, and in all of the model area south of the Tamiami Trail with the exception of the southeastern marl prairies of ENP. Values for BCNP are equivalent under the two regimes for all years in all but the easternmost and southernmost portions. For most years, index values for the eastern edge of BCNP are slightly higher under F2050, while the 10-mile Marl and East Slough areas generally show higher values under C1995. Small deteriorations in deer breeding potential values are seen under C1995 relative to F2050 in WCA-1, WCA-3A south and (in all but the wettest years) WCA-3B. Note that in both scenarios, the BPI is quite low throughout the entire region, with higher values limited in all but the driest years to Long Pine Key and portions of BCNP.

The performance of the scenarios during a "typical" year (1977, Fig. FEBD77FR.PDF), is very similar to the long-term average discussed above, although the overall area with high BPI values is reduced from the mean in the single year analysis.

During a high rainfall year (1969, which was not an exceptionally high water year, Fig. FEBD69FR.PDF), the same pattern persists, with the higher relative index values resulting from F2050 in WCA's 1 and 3, as in the long-term average. For this year, the F2050 regime produces higher index values relative to C1995 in the deep water areas of WCA3-A than in wetter years, when BPI's are zero for both scenarios. During these wet conditions, values of the deer breeding potential index were very low throughout most of the region, with high values concentrated in central and northern BCNP and in Long Pine Key. Similar patterns occur in other wet years, including 1970 (Fig. FEBD70FR.PDF), 1983 (Fig. FEBD83FR.PDF), and 1995 (Fig. FEBD95FR.PDF), with an additional area of improvement seen for C1995 for these wetter years in WCA3-B.

In the dry year of 1990, the extent of positive differences (higher values for C1995, indicated by yellow to gold colors in central panel, Fig. FEBD90FR.PDF) is reduced, but the magnitude of these differences increases in northern WCA-3A.

D-C.5.3.1 Conclusion

The current Breeding Potential analyses suggest distinct spatial trends in effects of the F2050 hydrologic scenario compared to C1995.

Advantages under the F2050 scenario are limited to WCA-1 and WCA-3, where deer stranding and deaths may occur during high water events, and the southeastern marl prairies of ENP. This improvement reflects the production under F2050 of somewhat drier conditions in the impounded areas north of Tamiami Trail, providing a longer period of water depths that deer can tolerate. However, somewhat wetter conditions are produced in the natural areas to the south of Tamiami Trail, where C1995 BPI values are generally higher. In the areas with potentially high breeding index values for deer there is either little difference between the BPI values produced by C1995 and F2050 (north and northwestern portions of BCNP), or C1995 values are slightly higher in Long Pine Key and surrounding short hydroperiod marshes.

D-C.5.4 Alternative A vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative A versus F2050 (Revised) on the Breeding Potential of White-tailed Deer in South Florida

Because of differential spatial effects of proposed hydrologic modifications for south Florida, when we compare the results of an alternative scenario with those of a base scenario some regions of the model area may show changes favorable to deer breeding for a given year, while other regions for the same year may reflect a deterioration of conditions. This is the case when we compare Alternative A with F2050.

Figure FABDMYFR.PDF shows mean values over the 31 year simulation period (1965-1995) for the ATLSS Breeding Potential Index (BPI) for white-tailed deer. As indicated in the central panel of this set of three maps, the Alternative A hydrologic regime produces average BPI values which differ only slightly from those of F2050 throughout most of the modeled region, indicated by the gray, yellow and light blue colors, representing no difference or small positive or negative differences, respectively (see also Table FABDDIFF.TXT, which lists mean BPI values for the various subregions delimited for evaluating ecological responses). The spatial pattern of these differences changes throughout the simulation period, with intensity and extent of differences varying with relative wetness of individual years. In the mean map, higher BPI values are seen under Alternative A in the Holey

Land WMA, a few scattered sites in central WCA-3A north, East Slough, the northern end of 10-Mile Marl, the northwestern portion of Shark River Slough, and a few sites in the southeastern marl prairies of ENP. BPI values are equivalent or slightly higher under F2050 for all other portions of the model area, including WCA-1, WCA-2A, WCA-2B, most of WCA-3A, WCA-3B, central and southern Shark River Slough, and most of Big Cypress National Preserve (BCNP) and Everglades National Park (ENP). Note that in both scenarios, the BPI is quite low throughout the entire region, with higher values limited in all but the driest years to Long Pine Key and portions of BCNP.

Relative performance of the scenarios during a "typical" year (1977, Fig. FABD77FR.PDF) differs from the long-term average discussed above in several respects. The overall area with high BPI values is reduced from the mean in the single year analysis. Positive differences for Alternative A for the Holey Land WMA are higher than in the mean map and extend into the Rotenberger WMA. Additional areas of advantage for Alternative A are seen along L-67 canal in WCA-3A and 3B and in WCA-2B. 1977 is the only simulation year for which Alternative A produces higher values in WCA-2B. BPI values are equivalent for 1977 under the two scenarios for the East Slough/10 Mile Marl/NW Shark River Slough area, where higher BPI's were seen for Alternative A in the mean map.

The pattern seen in wet years is similar to that seen in the long-term average, with the extent of areas of Alternative A advantages expanding as wetness increases. During a high rainfall year (1969, which was not an exceptionally high water year, Fig. FABD69FR.PDF), patterns and extents are very similar to mean patterns, with areas of Alternative A advantage restricted to the Holey Land WMA, north central WCA-3A north, and the East Slough/northern 10-mile Marl/NW Shark River Slough area. In other wet years, including 1970 (Fig. FABD70FR.PDF), 1983 (Fig. FABD83FR.PDF), and 1995 (Fig. FABD95FR.PDF), the area of higher BPI values for Alternative A around East Slough expands into southwestern and central WCA-3A and northern Shark River Slough and parts of WCA-3B. In the very wet year of 1995 Alternative A BPI's are higher in southeastern BCNP and all of WCA-3A and 3B. During these wet conditions, values of the deer breeding potential index are very low throughout most of the region, with high values concentrated in central and northern BCNP and in Long Pine Key. For these wetter years, BPI values become zero under both hydrological regimes in the deeper water portions of WCA-3A south and 3B, and through the central flowway of Shark River Slough. Progressive loss of deer habitat in WCA-3B and Shark River Slough is seen first under Alternative A and then with F2050 also as conditions become wetter, while progressive loss of habitat in WCA-3A south is more extensive under F2050.

In the dry year of 1990, the extent of positive differences (higher values for Alternative A, indicated by yellow to gold colors in the central panel, Fig.

FABD90FR.PDF), is reduced, restricted to the Holey Land/Rotenberger WMA's, and very small scattered sites elsewhere in the model area. The magnitude of relative advantages for F2050 increases in WCA-1 and parts of North Taylor Slough. BPI values are generally much higher overall in dry years such as as 1989 (not shown) and 1990.

D-C.5.4.1 Conclusion

The current Breeding Potential analyses suggest distinct spatial trends in predicted effects of the Alternative A hydrologic scenario compared to F2050. In dry years, predicted foraging conditions for deer are equivalent or more favorable under F2050 in most parts of the model area, with the exception of the Holey Land and Rotenberger WMA's.

As more water is added to the system, BPI's decline overall, the deeper water areas become inhospitable to deer, and areas of more favorable predicted breeding conditions for deer under Alternative A appear in north central WCA-3A, along L-67 in WCA-3A south, and in the East Slough/northern 10-Mile Marl/northwestern Shark River Slough areas. In the very wet year of 1995, these areas coalesce to form a single continuous unit through the central portion of the model area. Elsewhere, BPI's are equivalent or F2050 values are slightly higher. This pattern reflects the production under F2050 of somewhat drier conditions in the central flow-way of Shark River Slough and in the impounded areas of the WCA's (in all but the wettest years), providing a slightly longer period of water depths that deer can tolerate in these areas. Alternative A produces consistently drier conditions in the Holey Land WMA and, as conditions become wetter, in expanding areas around East Slough and portions of WCA-3A south and WCA-3B.

Because Alternative A produces somewhat drier conditions in deep water portions of WCA-3A and 3B in very wet years, fewer deer mortalities could be expected in these impounded areas during high water events. In areas with potentially high breeding index values for deer (northern portions of BCNP and Long Pine Key), there is little difference between the BPI values produced by Alternative A and F2050.

D-C.5.5 Alternative B vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative B versus F2050 on the Breeding Potential of White-tailed Deer in South Florida

Because of differential spatial effects of proposed hydrologic modifications for south Florida, when we compare the results of an alternative scenario with those of a base scenario some regions of the model area may show changes favorable to deer breeding for a given year, while other regions for the same year may reflect a deterioration of conditions. This is the case when we compare Alternative B with F2050.

Figure FBBDMYFR.PDF shows mean values over the 31 year simulation period (1965-1995) for the ATLSS Breeding Potential Index (BPI) for white-tailed deer. As indicated in the central panel of this set of three maps, the Alternative B hydrologic regime produces average BPI values which differ only slightly from those of F2050 throughout most of the modeled region, indicated by the gray, yellow and light blue colors, representing no difference or small positive or negative differences, respectively (see also Table FBBDDIFF.TXT, which lists mean BPI values for the various subregions delimited for evaluating ecological responses). The spatial pattern of these differences, however, is distinctive, and this pattern is consistent throughout the simulation period, with intensity and extent of differences varying with relative wetness of individual years. Higher BPI values are seen under Alternative B in WCA-2B, the Holey Land WMA, central WCA-3A north deep water portions of WCA-3A south, East Slough, and the northern half of the 10-Mile Marl area. BPI values are equivalent or slightly higher under F2050 for all other portions of the model area, including WCA-1, WCA-2A, WCA-3B, central and southern Shark River Slough, and most of Big Cypress National Preserve (BCNP) and Everglades National Park (ENP). Note that in both scenarios, the BPI is quite low throughout the entire region, with higher values limited in all but the driest years to Long Pine Key and portions of BCNP.

The performance of the scenarios during a "typical" year (1977, Fig. FBBD77FR.PDF) is similar to the long-term average discussed above, although the overall area with high BPI values is reduced from the mean in the single year analysis. The positive differences for ALT-B for the Holey Land WMA are higher than in the mean map and extend into the Rotenberger WMA, while BPI values are equivalent for 1977 under the two scenarios for East Slough and WCA-2A.

During a high rainfall year (1969, which was not an exceptionally high water year, Fig. FBBD69FR.PDF), the same pattern persists, with higher relative index values resulting from F2050 in WCA-1, northern WCA-2A, WCA-3A south (except for the deep water portions along L-67) WCA-3B, and ENP, as in the long-term average. Similar patterns occur in other wet years, including 1970 (Fig. FBBD70FR.PDF), 1983 (Fig. FBBD83FR.PDF), and 1995 (Fig. FBBD95FR.PDF). The area of higher BPI values for Alternative B around East Slough expands in wet years into southwestern WCA-3A and northern Shark River Slough and in the very wet year of 1995 into southeastern BCNP and southwestern WCA-3A. During these wet conditions, values of the deer breeding potential index are very low throughout most of the region, with high values concentrated in central and northern BCNP and in Long Pine Key. For these wetter years, BPI values become zero under both hydrological regimes in the deeper water portions of WCA-3A south and 3-B, and through the central flowway of Shark River Slough. Progressive loss of deer habitat in WCA-3B and Shark River Slough is seen first under Alternative B and then with F2050 also as conditions become wetter while progressive loss of habitat in WCA-3A south is seen first under F2050.

In the dry year of 1990, the extent of positive differences (higher values for Alternative B, indicated by yellow to gold colors in the central panel, Fig. FBBD90FR.PDF), is reduced, restricted to the Holey Land/Rotenberger WMA's, a small area in north central WCA-3A and adjacent to L-67 in WCA-3A south, but the magnitude of these differences increases. The magnitude of relative advantages for F2050 increases in WCA-1, parts of WCA-3, and scattered sites within ENP. BPI values are generally much higher overall in dry years such as 1989 (not shown) and 1990.

D-C.5.5.1 Conclusion

The current Breeding Potential analyses suggest distinct spatial trends in predicted effects of the Alternative B hydrologic scenario compared to F2050. In dry years, predicted foraging conditions for deer are more equivalent or favorable under F2050 in most parts of the model area, with the exception of the Holey Land and Rotenberger WMA's, small areas in north central WCA-3A and along L-67 in WCA-3A south, and scattered sites in southwestern BCNP. As more water is added to the system, BPI's decline overall, the deeper water areas become inhospitable to deer, and areas of more favorable predicted breeding conditions for deer under Alternative B expand in WCA-2A south, WCA-2B, WCA-3A and the East Slough/northern 10-Mile Marl area. In the very wet year of 1995, these areas coalesce to form a single continuous unit through the central portion of the model area. Elsewhere, BPI's are equivalent or F2050 values are slightly higher. This pattern reflects the production under F2050 of somewhat drier conditions in most of ENP and in the impounded areas of WCA-1, WCA-3B, and (in all but the wettest years) west-central WCA-3 south, providing a longer period of water depths that deer can tolerate in these areas. Alternative B produces consistently drier conditions in the Holey Land WMA and in expanding areas of East Slough, WCA-2B and the deep-water portions of WCA-3A south. In areas with potentially high breeding index values for deer (northern portions of BCNP and Long Pine Key), there is little difference between the BPI values produced by Alternative B and F2050.

D-C.5.6 Alternative C vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative C versus F2050 (Revised) on the Breeding Potential of White-tailed Deer in South Florida

Because of differential spatial effects of proposed hydrologic modifications for south Florida, when we compare the results of an alternative scenario with those of a base scenario some regions of the model area may show changes favorable to deer breeding for a given year, while other regions for the same year may reflect a deterioration of conditions. This is the case when we compare Alternative C with F2050.

Figure FCBDMYFR.PDF shows mean values over the 31 year simulation period (1965-1995) for the ATLSS Breeding Potential Index (BPI) for white-tailed deer. As indicated in the central panel of this set of three maps, the Alternative C hydrologic regime produces average BPI values which differ only slightly from those of F2050 throughout most of the modeled region, indicated by the gray, yellow and light blue colors, representing no difference or small positive or negative differences, respectively (see also Table FCBDDIFF.TXT, which lists mean BPI values for the various subregions delimited for evaluating ecological responses). The spatial pattern of these differences, however, is distinctive, and this pattern is consistent throughout the simulation period, with intensity and extent of differences varying with relative wetness of individual years. Higher BPI values are seen under Alternative C in southern WCA-2A and WCA-2B, the Holey Land WMA, central WCA-3A north of Alligator Alley, East Slough, and the northern half of the 10-Mile Marl area. BPI values for most of Big Cypress National Preserve (BCNP) are equivalent for the two water regimes, while values for Everglades National Park (ENP) are slightly higher under F2050 except for a few scattered sites in southeastern ENP. Values are also slightly higher under F2050 for WCA's 1, 3A south, and 3B. Note that in both scenarios, the BPI is quite low throughout the entire region, with higher values limited in all but the driest years to Long Pine Key and portions of BCNP.

The performance of the scenarios during a "typical" year (1977, Fig. FCBD77FR.PDF) is similar to the long-term average discussed above, although the overall area with high BPI values is reduced from the mean in the single year analysis. The positive differences for ALT-C for the Holey Land WMA are higher than in the mean map and extend into the Rotenberger WMA, and BPI values are equivalent for East Slough and WCA-2A.

During a high rainfall year (1969, which was not an exceptionally high water year, Fig. FCBD69FR.PDF), the same pattern persists, with higher relative index values resulting from F2050 in WCA's 1, northern 2A, 3A south and 3B, and in most of ENP, as in the long-term average. Similar patterns occur in other wet years, including 1970 (Fig. FCBD70FR.PDF), 1983 (Fig. FCBD83FR.PDF), and 1995 (Fig. FCBD95FR.PDF). The area of higher BPI values for Alternative C around East Slough expands into southwestern WCA-3A and northern Shark River Slough and in the very wet year of 1995 into southeastern BCNP and southwestern WCA-3A. During these wet conditions, values of the deer breeding potential index are very low throughout most of the region, with high values concentrated in central and northern BCNP and in Long Pine Key. For these wetter years, BPI values become zero under both hydrological regimes in the deeper water portions of WCA-3A south and 3-B, and through the central flowway of Shark River Slough. This progressive loss of deer habitat is seen first under Alternative C and then with F2050 also as conditions become wetter.

In the dry year of 1990, the extent of positive differences (higher values for Alternative C, indicated by yellow to gold colors in the central panel, Fig. FCBD90FR.PDF) is reduced to the Holey Land/ Rotenberger WMA's and a small area in north central WCA-3A. The magnitude of relative advantages for F2050 increases in WCA-1 and parts of WCA-3. BPI values are generally much higher overall in dry years such as 1989 (not shown) and 1990.

D-C.5.6.1 Conclusion

The current Breeding Potential analyses suggest distinct spatial trends in predicted effects of the Alternative C hydrologic scenario compared to F2050. In dry years, foraging conditions for deer are more favorable under F2050 in most parts of the model area, with the exception of the Holey Land and Rotenberger WMA's and a small area in north central WCA-3A. As more water is added to the system, BPI's decline overall, the deeper water areas become inhospitable to deer, and conditions under Alternative C become relatively more favorable in WCA-2A south, WCA-2B, and the East Slough/northern 10-Mile Marl area. Elsewhere, BPI's are equivalent or F2050 values are slightly higher. This pattern reflects the production under F2050 (in all but the wettest years) of somewhat drier conditions in the impounded areas of WCA-1 and WCA-3 and in most of ENP, providing a longer period of water depths that deer can tolerate. In the areas with potentially high breeding index values for deer (northern portions of BCNP and Long Pine Key), there is little difference between the BPI values produced by Alternative C and F2050.

D-C.5.7 Alternative D vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative D versus F2050 (Revised) on the Breeding Potential of White-tailed Deer in South Florida

Figure FDBDMYFR.PDF shows mean values over the 31 year simulation period (1965-1995) for the ATLSS Breeding Potential Index (BPI) for white-tailed deer. As indicated in the central panel of this set of three maps, the Alternative D hydrologic regime produces average BPI values which differ only slightly from those of F2050 throughout most of the modeled region, indicated by the gray, yellow and light blue colors, representing no difference or small positive or negative differences, respectively (see also Table FDBDDIFF.TXT, which lists mean BPI values for the various subregions delimited for evaluating ecological responses). The spatial pattern of these differences, however, is distinctive, and this pattern is consistent throughout the simulation period, with intensity and extent of differences varying with relative wetness of individual years. Higher BPI values are seen under Alternative D in southern WCA-2A and WCA-2B, the Holey Land WMA, central

WCA-3A north of Alligator Alley, East Slough, and the northern half of the 10-Mile Marl area. BPI values for most of Big Cypress National Preserve (BCNP) are equivalent for the two water regimes, while values for Everglades National Park (ENP) are slightly higher under F2050 except for a few scattered sites in southeastern ENP. Values are also slightly higher under F2050 for WCA's 1, 3A south, and 3B. Note that in both scenarios, the BPI is quite low throughout the entire region, with higher values limited in all but the driest years to Long Pine Key and portions of BCNP.

The performance of the scenarios during a "typical" year (1977, Fig. FDBD77FR.PDF) is similar to the long-term average discussed above, although the overall area with high BPI values is reduced from the mean in the single year analysis. The positive differences for ALT-D for the Holey Land WMA are higher than in the mean map and extend into the Rotenberger WMA, and BPI values are equivalent for East Slough and WCA-2A.

During a high rainfall year (1969, which was not an exceptionally high water year, Fig. FDBD69FR.PDF), the same pattern persists, with higher relative index values resulting from F2050 in WCA's 1, northern 2A, 3A south and 3B, and in most of ENP, as in the long-term average. Similar patterns occur in other wet years, including 1970 (Fig. FDBD70FR.PDF), 1983 (Fig. FDBD83FR.PDF), and 1995 (Fig. FDBD95FR.PDF). The area of higher BPI values for Alternative D around East Slough expands into southwestern WCA-3A and northern Shark River Slough. During these wet conditions, values of the deer breeding potential index are very low throughout most of the region, with high values concentrated in central and northern BCNP and in Long Pine Key. For these wetter years, BPI values become zero under both hydrological regimes in the deeper water portions of WCA-3A south and 3-B, and through the central flowway of Shark River Slough. This progressive loss of deer habitat is seen first under Alternative D and then with F2050 also as conditions become wetter.

In the dry year of 1990, the extent of positive differences (higher values for Alternative D, indicated by yellow to gold colors in the central panel, Fig. FDBD90FR.PDF) is reduced to the Holey Land/Rotenberger WMA's and a small area in north central WCA-3A. The magnitude of relative advantages for F2050 increases in WCA-1 and parts of WCA-3. BPI values are generally much higher overall in dry years such as 1989 (not shown) and 1990.

D-C.5.7.1 Conclusion

The current Breeding Potential analyses suggest distinct spatial trends in predicted effects of the Alternative D hydrologic scenario compared to F2050. In dry years, foraging conditions for deer are more favorable under F2050 in most parts of the model area, with the exception of the Holey Land and Rotenberger WMA's and a small area in north central WCA-3A. As more water is added to the system, BPI's decline overall, the deeper water areas become inhospitable to deer, and conditions under Alternative D become relatively more favorable in WCA-2A south, WCA-2B, and the East Slough/northern 10-Mile Marl area. Elsewhere, BPI's are equivalent or F2050 values are slightly higher. This pattern reflects the production under F2050 (in all but the wettest years) of somewhat drier conditions in the impounded areas of WCA-1 and WCA-3 and in most of ENP, providing a longer period of water depths that deer can tolerate. In the areas with potentially high breeding index values for deer (northern portions of BCNP and Long Pine Key), there is little difference between the BPI values produced by Alternative D and F2050.

D-C.6 SNAIL KITE INDEX MODEL

ATLSS
Snail Kite Index Model
Basic Model Description

Jane Comiskey, John Curnutt, and Louis Gross
The Institute for Environmental Modeling
University of Tennessee, Knoxville
Knoxville, TN 37996-1610

D-C.6.1 Statement of Limitations

The ATLSS Snail Kite Index (SKI) Model was developed as a crude indicator of potential habitat quality during the breeding season for snail kites in the Florida Everglades. All evidence suggests that the population dynamics for this species are influenced by environmental conditions occurring throughout its entire range in Florida. This model addresses only relative habitat quality within a limited area, ignoring larger spatial extent population dynamics that may have a much greater effect on this species than habitat quality in part of its range. Consequently, this model should not be interpreted to represent population dynamics or viability. The time scales at which evaluations of alternative scenarios are evaluated also are likely to be too short to encompass some long-term changes in habitat quality.

Particularly, stabilized hydrologic regimes may result in a slow degradation of habitat that may be overlooked at the time scales evaluated with this model. In addition, very little verification of this model's performance has been performed and several of its parameter values are "best guess" approximations, for which data are either currently lacking or have not yet been fully analyzed. A spatially explicit full demographic model for snail kites based on available data is currently under development as part of the ATLSS project.

D-C.6.2 Introduction

The snail kite (*Rostrhamus sociabilis*) is an endangered raptor whose distribution in the United States is restricted to the South Florida Ecosystem, including watersheds of the Everglades, Lake Okeechobee, Kissimmee River, and Upper St. Johns River. Because snail kites feed almost exclusively on one species of aquatic snail (the apple snail, *Pomacea paludosa*), their survival depends directly on the hydrologic functioning of these watersheds. Each of these watersheds has experienced, and continues to experience, substantial degradation, resulting in the current planning for what probably will become the largest ecosystem restoration ever undertaken. Although other endangered species occur within the ecosystem, snail kites are probably the only species restricted to the watersheds within the South Florida Ecosystem and dependent on the entire network of wetlands within this ecosystem. Over half of the wetlands within central and southern Florida have been lost during the past century and those that remain have been highly fragmented and severely degraded (Weaver et al. 1994). This degradation has prompted planning for ambitious restoration efforts (e.g., the Central and South Florida Project Restudy, Kissimmee River Restoration, and the South Florida Ecosystem Restoration initiative). Because of the snail kite's restricted range and because their population is highly dependent on the success of restoration efforts, the snail kite is a key species to monitor throughout the restoration process.

D-C.6.3 Model Development

Temporal Constraints. - Although snail kites in Florida can potentially lay eggs in all months of the year, there is a very distinct seasonal distribution of nest initiations. Nest initiations begin as early as November, but in most years widespread initiations usually do not begin until January or February. During most years nest initiations decrease markedly after June, but may extend through July in some years. For this model we defined the primary breeding season as the period from January-July (reviewed by Bennetts and Kitchens 1997).

Suitable conditions for any given year are required to persist for a minimum of 16 weeks during the primary breeding season (January-July). This is based on the time required to complete one breeding cycle, including nest building (10 days), egg laying (2-day intervals with incubation beginning with the 2nd egg), incubation

(27 days), the nestling period (30 days), and a post-fledgling period (45 days) (Beissinger 1984, Beissinger and Snyder 1987, Snyder et al. 1989).

Relative Habitat Quality - Available evidence suggests that suitable conditions for snail kite breeding are influenced by each of three aspects of hydrology that occur at different temporal scales (Bennetts et al. 1998). Suitable conditions at each scale are necessary, but none is sufficient alone to delimit suitable breeding habitat for snail kites. The hydrology at each of these scales regulates a different aspect of the environment important to snail kites. Thus our Snail Kite Index (SKI) takes on the values of 0 (unsuitable), 1 (marginal), or 2 (suitable) for each landscape grid cell. A value of 0 for any of the hydrologic measures results in a cell BPI value of 0 for that year. Otherwise, the cell is assigned the lowest non-zero factor value.

The first hydrologic factor is daily water level (depth). The empirical relationship between snail kites' use of a given habitat and water depth has been well recognized and has been illustrated by the distribution of nests or foraging birds with respect to water depth (e.g., Stieglitz and Thompson 1967, Sykes 1987, Bennetts et al. 1988). The response of snail kites to changing water depth can be seen in shifts in spatial distribution (Bennetts and Kitchens 1997, Bennetts et al. 1998). For example, the spatial distribution of nesting kites within Water Conservation Area (WCA) 3A, a 237,000 ha impoundment used extensively for nesting during the past three decades, was similar for 1992, 1993, and 1994. During the 1995-breeding season, water depths were at record high levels throughout the Everglades as a result of tropical storm Gordon the previous fall. The distribution of nesting kites within WCA-3A shifted dramatically to the north during 1995 compared to observations for the previous three years. Birds moved from areas that were too deep to areas of higher elevation with correspondingly shallower water (Bennetts and Kitchens 1997). When water levels receded the following year, the distribution of nesting birds shifted back to the south where they had been prior to the high water event.

Water depth is probably important for snail kites because of how it affects apple snail behavior and availability. Water depths that are too shallow (e.g., < 10-cm) may impede the movement of snails, as submergent vegetation is densely compacted within the water column (Darby et al. 1997). Shallow water during certain seasons also may result in water temperatures rising above the tolerance level of snails (Darby et al. 1997). Bennetts et al. (1988) suggested that a minimum of 20-cm at the time of initiation is required for suitable breeding conditions, with some drying expected during the nesting season. Our lower limit for suitable breeding conditions with respect to water depth is 20-cm at the time of initiation (i.e., during the primary breeding season), and depth must remain above 10-cm for at least the time required to successfully raise a brood (110 days).

Water that is too deep may also be unsuitable for breeding snail kites. Water deeper than 1-m may lack sufficient oxygen to support apple snails (Hanning 1978) and/or sufficient vegetation that would enable snails to climb near the surface, where they are available to kites (Darby et al. 1997). The distribution of water depths in the Everglades typically ranges from 10 to 115-cm. Snail kite nests at alligator holes or other depressions are occasionally built over deeper water (Bennetts et al. 1994). Thus, we defined an upper limit of suitable depths to be 115-cm.

The second hydrologic factor considered is the time since dry-down at a given location. This factor contributes both to apple snail population dynamics and to the maintenance of plant communities comprising snail kite habitat. Florida apple snails are aquatic and have a limited capacity to survive dry conditions (Little 1968), although the timing of drying may be more important to the overall population dynamics than just the occurrence of drying (Darby et al. 1997). However, drying events result in periodic reductions in the availability of snail kite food resources regardless of whether snail survival is significantly affected. Based on preliminary comparisons of numbers of kites counted during the annual survey before and after drying events in several wetlands, relative habitat quality on average is about 50% of pre-drying conditions the year following the drying event, 85% two years following and fully recovered by three years. Thus, we consider relative habitat quality to be unsuitable during the year that an area dried, marginal the following year, and suitable after two years. However, recent work by Darby et al. (1997) has indicated that the timing of a drying event may be a critical factor in how it affects the apple snail population. Snails hatched during the previous year undergo an almost complete die-off during May-July following reproduction. Thus the cohort that provides the breeding potential for the next year are those that hatched in the preceding year. Given that the peak of egg laying (for snails) occurs from March-May, a drying event that occurs before May can deplete the cohort of breeders for the following year. Consequently, if a drying event occurs before May, we consider habitat to be marginal for an additional year, while the breeding stock replenishes.

Although the occurrence of drying events may affect apple snail populations, the absence of drying results in changes in plant communities. There is a considerable body of evidence regarding the tolerances to prolonged inundation of the plant species that comprise suitable habitat (e.g., Craighead 1971, U.S. Department of Interior 1972, McPherson 1973, Worth 1983, Dineen 1972, 1974, Gunderson 1994). Observable changes in plant communities in the absence of drying have occurred after 5-6 years (Ager and Kerce 1970, U.S. D.I. 1972), and some plant communities comprising kite habitat can be replaced by other communities in as little as 9-10 years (Milleson 1987). Thus, we consider habitat to be in the process of deterioration after 5 years of continuous flooding; it is considered unsuitable after 10 years of continuous flooding.

The third hydrologic factor is a cumulative effect of the longer temporal pattern of repeated drying events. In particular, the frequency of drying events is expressed as a "hydrologic regime" and is measured as long-term (10-yr) hydroperiod (the proportion of time an area is inundated over a 10-year period). This long-term pattern is the primary hydrologic scale at which plant communities are regulated; although vegetation is also regulated by still slower processes that affect climatic regimes and sea level rise (Gunderson 1994). Although rapid degradation of habitat occurs if a site is continuously inundated, most sites experience drying at intervals less than that which would result in direct transitions of plant communities. Habitat changes often occur slowly and incrementally, with periods of at least partial rejuvenation resulting from periodic drying. Because of the extreme lack of topographic relief across the central and southern Florida wetland landscape, relatively small changes in elevation correspond to relatively large changes in hydrology. Consequently, differences of a few centimeters in elevation can have profound effects on plant communities and ultimately on the quality of the habitat for kites. The response of snail kites at this scale also can be illustrated by changes in their spatial distribution over longer time periods. For this index model, cells which are inundated less than 80% or greater than 98% of the time over a ten-year are considered unsuitable as snail kite habitat; cells with inundation periods of 80-85% and 95-98% are considered marginal; and cells with 85-95% inundations periods are considered suitable.

Acknowledgments

The authors would like to thank Robert Bennetts for frequent and productive input into the development of this model and for reviewing our results.

Output associated with the ATLSS Snail Kite Index Model.

In accordance with ATLSS file naming conventions, each file name will consist of the characters: UVXXYYZZ.EXT

"U" or "_" => the Base, typically F for the F2050 base or E for the C1995 base
"V" or "_" => the alternative scenario or base
"XX" => "SK" for the ATLSS Snail Kite Index Model
"YYZZ" => 4 character mnemonic, described below
"."
"EXT" = "PDF" or "TXT" or "DOC" => PDF, tabular text or documentation

ATLSS Snail Kite Index Model

1. Maps

Map outputs used to characterize results of the Snail Kite Index Model will consist of eight image files in PDF file format. Each map shows a shows a "Set" of model results, comparing one SFWMM hydrologic scenario to another, following the conventions for ATLSS comparisons of two model runs. Each map has three panels. The left panel displays index values for either an alternative or base scenario; the right panel displays index values for a base scenario (e.g., the Future without Project Conditions Case, or F2050). The middle panel displays the cell-by-cell difference between index values for the two compared scenarios (e.g., ALT-5 minus F2050).

Grid cells in the left and right panels are color-coded to represent the (positive) values of the displayed index, which range between 0 and 1. Cell colors in the center panel represent either positive (shades of gold) or negative (shades of blue) differences between index values displayed in the left panel and those in the right panel. Color keys are provided at the bottom of each map. Each map depicts the model area at either a Fine (500-meter x 500-meter) or Coarse (2-mile) scale of resolution.

For each of six selected years, images will provide a spatial display of index values for that year. In addition, an image file is provided for the mean of all simulated years. The selected years include years with high, low, and typical rainfall, and several additional years that serve to highlight differences between the compared scenarios.

The mnemonic characters are composed according to the convention:
"YY" = Last two digits of the year
"ZZ" = CR - Coarse (2 mile) resolution, FR - Fine (500 meter) resolution

Listing of ATLSS Snail Kite Index map files:

File Name	Time Period
UVSK69ZZ.PDF	A High Rainfall Year (1969)
UVSK70ZZ.PDF	Highlight Scenarios (1970)
UVSK77ZZ.PDF	A Typical Rainfall Year (1977)
UVSK83ZZ.PDF	Highlight Scenarios (1983)
UVSK90ZZ.PDF	A Low Rainfall Year (1990)
UVSK95ZZ.PDF	Highlight Scenarios (1995)
UVSKMYZZ.PDF	Mean of All Years (1965->1995)

2. Time Series

Time series sets associated with the ATLSS Snail Kite Index will display index values for five subregions: WCA-1, WCA-2A, WCA-2B, WCA-3A and WCA-3B.

These show percentage of available habitat in which suitable habitat conditions occurred for each simulation year.

File Name	Description
UVSKTSZZ.PDF	Percentage of available habitat in which suitable habitat conditions occurred for each simulation year in each of three subregions.

3. Histograms None.

4. Tables None.

D-C.6.4 F2050 (Revised) vs. C1995 (Revised)

Assessment of the Effects of Proposed Water Regimes F2050 (Revised) vs. C1995 (Revised) on Snail Kites in South Florida

D-C.6.4.1 Caveats

The vagility of the Snail Kite in Florida is evident in both its highly variable breeding distribution and its propensity to disperse great distances between breeding seasons. Our model area incorporates only a part of the Kite's potential breeding range - albeit a very important part. Furthermore, there are many factors affecting the spatial and temporal dynamics of nest placement and breeding success. For Kites, as for most raptors, these include the density and availability of prey, the presence of suitable nesting sites, and the ability to establish and maintain a pair bond. Other factors such as temperature, predation, and water quality may also be important. Our Snail Kite model is driven solely by hydrology and the predicted effects of hydrology on the production and availability of Apple Snails (the Kite's primary prey). Thus, results of the model should be interpreted more as indices of foraging conditions than as breeding potentials. However, since we are interested only in the level of foraging that is sufficient for successful breeding, our output refers only to prey densities and foraging conditions that occur during the Kite breeding season. Thus, if an area has an index value of zero it may still have snails, but not at a sufficient density, or under the correct hydrologic conditions that would allow a successful Kite nesting cycle. Given this caveat, for the sake of simplicity we will refer to the model output as a foraging condition index.

As noted above, Kite breeding distribution is highly variable. However, the Water Conservation areas (WCA-1, WCA-2A, WCA-2B, WCA-3A, and WCA-3B) typically hold a large proportion of breeding Kites in most years. Kites have nested south of the WCAs in Everglades National Park intermittently, but, perhaps because of low habitat suitability, this area has not served as a major Kite breeding ground. Our interpretation of the model results, therefore, will focus on the WCA's.

D-C.6.4.2 Index Results

Figure FESKMYFR.PDF shows the 31-year (1965-1995) average values of Snail Kite Indices (SKI) for foraging conditions across the model area. As indicated in the central panel of this set of three maps, C1995 produces average SKI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FESKMYFR.PDF) for nearly all of WCA-3B, most of WCA-2B, the northern half of WCA-2A and a large part of WCA-3A (south). F2050 results in higher SKI values for northern WCA-3A, the southern half of WCA-2A, and the larger sloughs of Everglades National Park. WCA-1 shows great spatial variation in which scenario has higher SKI values, with higher values under F2050 dominating at the downstream edge of the area.

The long-term average discussed above masks divergent effects of hydrologic conditions for individual years. During a "typical" year (1977, Fig. FESK77FR.PDF) the spatial extent of foraging conditions suitable for Kite breeding is greatly reduced under F2050 - producing higher SKI values relative to C1995 only for portions of WCA-2B. Conversely, under C1995 mid-range SKI values occur over WCA-1, southern WCA-3A, a portion of WCA-3B, and the Holey Land WMA.

During a high rainfall year (1969, Fig. FESK69FR.PDF, which was not an exceptionally high water year) and a high surface water year (1970, Fig. FESK70FR.PDF), Snail Kite SKI's are high across much of the model area under both scenarios. In these years, there are spatial differences in SKI between the two scenarios - C1995 produces equivalent or higher SKI values over all of WCA-1, most of WCA-3A (south), WCA-3B and part of WCA-2B, relative to F2050. F2050 produces higher SKI's over central WCA-2A and northern WCA-3A as well as part of the Holey Lands WMA. In Everglades National Park, central Shark River Slough has higher SKI values under C1995, while in the periphery of the Slough F2050 produces higher SKI's.

During extremely wet years the Snail Kite SKI pattern becomes very complex. Water levels that are too high limit the availability of snails to Kites and the spatial extent of suitable foraging conditions contracts relative to less extreme high water years. During the years of 1983 and 1995 (Figs. FESK83FR.PDF and FESK95FR.PDF), F2050 produces higher SKI values for much of the model area relative to C1995, although there are considerable spatial variations in this. In 1983, WCA-2B, WCA-3B and the west-central portion of WCA-3A exhibit higher SKI values under C1995 relative to F2050. In 1995, F2050 provides predominantly higher SKI's relative to C1995, but C1995 again produces higher SKI's for WCA-2B and WCA-3B.

In the dry year of 1990 (Fig. FESK90FR.PDF), foraging conditions suitable for breeding are practically non-existent across the model area under both F2050 and C1995. F2050 does provide a small area of intermediate SKI values in the Holey Lands WMA, but the overall difference between the two scenarios is negligible.

Figures FESKT1FR.PDF and FESKT2FR.PDF are temporal plots of total foraging potential realized for each of the WCAs and the mean across these selected subregions. Generally, both F2050 and C1995 show the same trajectory over time - increasing and decreasing in step, with index values falling below threshold levels proposed for successful breeding in most drought years. For WCA-2A there is virtually no difference between the two scenarios in total foraging potential realized over the period of record. For the remaining WCA's, C1995 tends to produce higher foraging potential relative to F2050 in most years - and always in wet and high water years (1969, 1970, 1983, 1995) for WCA-2B and WCA-3B.

D-C.6.4.3 Conclusion

Results of the model show clearly the compartmental nature of Snail Kite foraging habitat in southern Florida. In comparing two scenarios with relatively similar overall hydroperiod patterns, such as C1995 and F2050, it is difficult to determine the merits of one versus the other. Often, one scenario produces relatively higher SKI's in some regions while the other scenario gives higher values in other regions in the same year. Overall, C1995 produces higher Snail Kite SKI's under a wide range of hydrologic conditions across all regions relative to F2050, often showing a faster recovery from drought conditions. The differences are not great, and in extreme conditions F2050 can produce higher SKI's (e.g. drought years in WCA-2B).

D-C.6.5 Alternative A vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative A versus F2050 (Revised) on Snail Kites in South Florida

D-C.6.5.1 Index Results

Figure FASKMYFR.PDF shows the 31-year (1965-1995) average values of Snail Kite Indices (SKI) for foraging conditions across the model area. As indicated in the central panel of this set of three maps, Alternative A produces average SKI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FASKMYFR.PDF) for nearly all of WCA-1, central WCA-2A, the eastern edge of WCA-2B, practically all of WCA-3A and most of WCA-3B. F2050 results in higher SKI values for the southern part of WCA-3B, eastern WCA-2A, most of WCA-2B, the Holey Land WMA, East Slough and the central drainage of Northeast Shark Slough and Shark River Slough.

The long-term average discussed above masks divergent effects of hydrologic conditions for individual years. During a "typical" year (1977, Fig. FASK77FR.PDF) the spatial extent of foraging conditions suitable for Kite breeding is greatly reduced under both scenarios. Alternative A provides a significant spatial distribution of relatively high SKI values in southern WCA-1, a small portion of WCA-3B, and central Shark River Slough. F2050 produces a scattering of low SKI values in WCA-2A and 2B, and moderate values in northern WCA-3A and the Holey Land WMA.

In the dry year of 1990 (Fig. FASK90FR.PDF), foraging conditions suitable for breeding are practically non-existent across the model area under both F2050 and Alternative A. F2050 does provide a small area of intermediate SKI values in the Holey Lands WMA. Alternative A does the same for southern WCA-1 and a small area straddling Northeast Shark Slough and Shark Slough. Overall, the difference between the two scenarios under dry conditions is negligible.

During a high rainfall year (1969, Fig. FASK69FR.PDF, which was not an exceptionally high water year), Alternative A provides higher or equivalent SKI values, relative to F2050, in WCA-1, 2A, 2B, and 3B. Alternative A also provides equivalent or higher values across central WCA-3A and along the edges of Shark River Slough. F2050 produces moderately higher SKI values in parts of northern WCA-3A and the Holey Land WMA, and significantly higher values at the southern edge of WCA-3A and the central drainage of Shark River Slough.

During a high surface water year (1970, Fig. FASK70FR.PDF), F2050 again produces significantly higher SKI values, relative to Alternative A for the central Shark Slough drainage from the southern edge of WCA-3B south, and moderately higher values for the Holey Land WMA and northern East Slough. The remaining model area shows moderately higher SKI values under Alternative A, relative to F2050, and significantly higher values in WCA-3B and the edges of Shark River Slough. At even higher surface water conditions (1983, Fig. FASK83FR.PDF), SKI values under both scenarios are lower than those predicted for 1970, except in central Shark River Slough. Under these conditions F2050 produces higher SKI values for most of WCA-1, northwestern WCA-2A, northern WCA-2B, southern WCA-3A and 3B, Northeast Shark River Slough, Shark River Slough and East Slough, relative to Alternative A. Alternative A produces equivalent or higher SKI values, relative to F2050, in northern WCA-3A, the periphery of WCA-3B and Shark River Slough, and the Holey Land WMA.

During extremely wet years (Fig. FASK95FR.PDF), F2050 dominates WCA-1, 2A, 3B, Northeast Shark Slough, Shark River Slough, and East Slough with higher SKI values, relative to Alternative A. Alternative A produces moderately higher SKI values across much of WCA-3A, and significantly higher values in the Holey Land WMA, northern WCA-3B, and the southern edge of the Shark River Slough drainage. SKI values are high across a large proportion of the landscape under both scenarios.

Figures FASKT1FR.PDF and FASKT2FR.PDF are temporal plots of total foraging potential realized for each of the WCA's and the mean across these selected subregions. For WCA-1 Alternative A realizes a larger proportion of potential relative to F2050 in all but the highest water conditions (FASKT1FR.PDF: top). There is no clear pattern in the potential realized under the two scenarios for WCA-2A and WCA-2B (FASKT1FR.PDF: middle and bottom). For WCA-3A, Alternative A generally equals the realized potential produced by F2050 in all but a few years of the model (FASKT2FR.PDF: top). For WCA-3B, Alternative A realizes more potential, relative to F2050, in all years but those where the above mentioned threshold is met (FASKT2FR.PDF: middle). Taken together, Alternative A out-performs F2050 in potential realized, but, when averaged over all regions, the difference is slight (FASKT2FR.PDF: bottom).

D-C.6.5.2 Conclusion

Alternative A produces higher SKI conditions under very dry to typical hydrologic conditions, relative to F2050. As water levels rise, F2050 provides higher SKI values across much of the area. In WCA-3A, an important area for Kites if only by its large size, there is little difference between the scenarios. Thus, each of these scenarios provides a substantial amount of potential kite foraging/breeding area under most conditions. In critical drier years, however, Alternative A provides more than F2050.

D-C.6.6 Alternative B vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative B versus F2050 on Snail Kites in South Florida

D-C.6.6.1 Index Results

Figure FBSKMYFR.PDF shows the 31-year (1965-1995) average values of Snail Kite Indices (SKI) for foraging conditions across the model area. As indicated in the central panel of this set of three maps, Alternative B produces average SKI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FBSKMYFR.PDF) for nearly all of WCA-1, the northern half of WCA-2A, the southern half of WCA-2B, all of WCA-3B and most of WCA-3A. F2050 results in higher SKI values for the far northern and southern parts of WCA-3A, the southern half of WCA-2A and most potential kite foraging habitat south of Tamiami Trail.

The long-term average discussed above masks divergent effects of hydrologic conditions for individual years. During a "typical" year (1977, Fig. FBSK77FR.PDF) the spatial extent of foraging conditions suitable for Kite breeding is greatly reduced under both scenarios. Alternative B provides a significant spatial distribution of relatively high SKI values in southern WCA-1, south and east WCA-3A and a small portion of WCA-3B. Alternative B also produces low to moderate SKI values in the Holey Land WMA. Conversely, F2050 produces very little in the way of SKI values. Under the "typical" hydrologic conditions, F2050 produces a scattering of low SKI values in WCA-2A and B, and moderate values in the Holey Land WMA.

In the dry year of 1990 (Fig. FBSK90FR.PDF), foraging conditions suitable for breeding are practically non-existent across the model area under both F2050 and Alternative B. F2050 does provide a small area of intermediate SKI values in the Holey Lands WMA, as does Alternative B (but to a lesser extent). Overall difference between the two scenarios under dry conditions is negligible.

During a high rainfall year (1969, Fig. FBSK69FR.PDF, which was not an exceptionally high water year), Alternative B is clearly more advantageous to producing high SKI values across most of the model area, relative to F2050. Alternative B provides higher SKI values across all of southern WCA-3A and most of WCA-3B, relative to F2050. Alternative B also provides higher values in all of WCA-1, parts of WCA-2A, southern WCA-2B, and even the northern edge and center of Shark River Slough in Everglades National Park. F2050 produces moderately higher SKI values in parts of northern WCA-3A, and in central and northern WCA-2A relative to Alternative B. F2050 also produces higher SKI values in Northeast Shark Slough and significantly higher values in southern Shark River Slough.

During a high surface water year (1970, Fig. FBSK70FR.PDF), the distribution of SKI values and the differences between the scenarios is similar to the conditions described above. Under high surface water conditions, however, SKI values are higher under F2050, diminishing the magnitude of the differences between the scenarios. At even higher surface water conditions (1983, Fig. FBSK83FR.PDF), SKI values under both scenarios are lower than those predicted for 1970. Under these conditions F2050 produces higher SKI values for most of WCA-1, southern WCA-3A, Northeast Shark River Slough, Shark River Slough and East Slough, relative to Alternative B. Alternative B produces equivalent or higher SKI values, relative to F2050, in western WCA-3A, WCA-3B and the Holey Land WMA.

During extremely wet years (Fig. FBSK95FR.PDF), SKI values are high across a large proportion of the landscape under both scenarios. However, under

Alternative B, water levels are too high in parts of each of the WCA's, limiting the availability of snails to Kites. F2050, therefore, produces higher SKI values for much of the model area relative to Alternative B, although considerable spatial variations are seen, most notably in WCA-3B and south of Tamiami Trail, where Alternative B provides slightly higher SKI values.

Figures FBSKT1FR.PDF and FBSKT2FR.PDF are temporal plots of total foraging potential realized for each of the WCA's and the mean across these selected subregions. Generally, both F2050 and Alternative B show the same trajectory over time, increasing and decreasing in step with index values falling below threshold levels proposed for successful breeding in most drought years. For WCA-1 a larger proportion of potential is realized under Alternative B relative to F2050 in all but the highest water conditions (FBSKT1FR.PDF: top). There is no clear pattern in the potential realized under the two scenarios for WCA-2A and WCA-2B (FBSKT1FR.PDF: middle and bottom). For WCA-3A Alternative B equals or exceeds the realized potential produced by F2050 in all but the last four years of the simulation (FBSKT2FR.PDF: top). For WCA-3B, Alternative B realizes more potential, relative to F2050, in all years but those where the above mentioned threshold is met (FBSKT2FR.PDF: middle). Taken together, Alternative B out-performs F2050 in potential realized under conditions present early in the simulation and is roughly equivalent from 1980 onwards (FBSKT2FR.PDF: bottom).

D-C.6.6.2 Conclusion

Alternative B produces higher SKI conditions under very dry to typical hydrologic conditions, relative to F2050. This is also true in moderately high water years. However, as water levels rise, F2050 provides higher SKI values across much of the area, most notably in WCA-3A. Thus, overall Alternative B outperforms F2050 under most conditions, but in extremely wet years the opposite is true.

D-C.6.7 Alternative C vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative C versus F2050 (Revised) on Snail Kites in South Florida

D-C.6.7.1 Index Results

Figure FCSKMYFR.PDF shows the 31-year (1965-1995) average values of Snail Kite Indices (SKI) for foraging conditions across the model area. As indicated in the central panel of this set of three maps, Alternative C produces average SKI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FCSKMYFR.PDF) for nearly all of WCA-1, the southern half of WCA-2B, the northern half of WCA-3B and a large part of WCA-3A (south). F2050 results in higher SKI values for northern WCA-3A, the southern half of WCA-3B and the larger sloughs of Everglades National Park. WCA-2A shows great spatial variation in which scenario has higher SKI values, with higher values under F2050 dominating at the downstream edge of the area.

The long-term average discussed above masks divergent effects of hydrologic conditions for individual years. During a "typical" year (1977, Fig. FCSK77FR.PDF) the spatial extent of foraging conditions suitable for Kite breeding is greatly reduced under both scenarios. There is no overlap in the spatial distribution of SKI values produced by F2050 and Alternative C. Alternative C provides scattered SKI values in southern WCA-1, WCA-3B, Northeast Shark Slough and Shark River Slough. F2050 produces SKI values in southern WCA-2B, western WCA-2A, sparsely in northern WCA-3A and the Holey Land WMA.

In the dry year of 1990 (Fig. FCSK90FR.PDF), foraging conditions suitable for breeding are practically non-existent across the model area under both F2050 and Alternative C. F2050 does provide a small area of intermediate SKI values in the Holey Lands WMA, and Alternative C does so in southern WCA-1, but the overall difference between the two scenarios is negligible.

During a high rainfall year (1969, Fig. FCSK69FR.PDF, which was not an exceptionally high water year), there are spatial differences in SKI between the two scenarios, Alternative C produces equivalent or higher SKI values over all available foraging habitat in WCA-1, northern WCA-2A, southern WCA-2B, most of WCA-3A (south) and northwestern WCA-3B, relative to F2050. F2050 produces higher SKI values over southern WCA-2A and northern WCA-3A as well as part of the Holey Lands WMA. In Everglades National Park, central Shark River Slough has higher SKI values under F2050, while in the periphery of the Slough Alternative C produces higher SKI's.

During a high surface water year (1970, Fig. FCSK70FR.PDF), the distribution of SKI values and the differences between the scenarios is similar to the conditions described above. Under high surface water conditions, however, SKI values are higher under F2050, diminishing the magnitude of the differences between the scenarios. At even higher surface water conditions (1983, Fig. FCSK83FR.PDF), SKI values under both scenarios are lower than those predicted for 1970. Under these conditions F2050 produces higher SKI values for most of WCA-1, western and northern WCA-3A, southern WCA-3B, Northeast Shark River Slough, Shark River Slough and East Slough, relative to Alternative C. Alternative C produces equivalent or higher SKI values, relative to F2050, in the remaining habitat and expands into the fringes around Shark Slough and the WCA's.

During extremely wet years (Fig. FCSK95FR.PDF), SKI values are high across a large proportion of the landscape under both scenarios. However, under Alternative C, water levels are too high in parts of each of the WCA's, limiting the availability of snails to Kites. F2050, therefore, produces higher SKI values for much of the model area relative to Alternative C, although there are considerable spatial variations in this.

Figures FCSKT1FR.PDF and FCSKT2FR.PDF are temporal plots of total foraging potential realized for each of the WCA's and the mean across these selected subregions. Generally, both F2050 and Alternative C show the same trajectory over time, increasing and decreasing in step with index values falling below threshold levels proposed for successful breeding in most drought years. For WCA-1 and WCA-2A, Alternative C realizes a larger proportion of potential relative to F2050 in most years, except under very high water conditions. There is no clear pattern in the potential realized under the two scenarios for WCA-2B. For WCA-3A and B, Alternative C again realizes more potential than F2050 in most years, including most high surface water years. Taken together, Alternative C out-performs F2050 in potential realized, except in the two years of highest surface water conditions (1983 and 1995) (FCSKT2FR.PDF: bottom).

D-C.6.7.2 Conclusion

Overall, Alternative C produces higher Snail Kite SKI's under a wide range of hydrologic conditions across all regions relative to F2050, often showing a faster recovery from drought conditions. As water depth increases, however, F2050 provides higher SKI values over a large part of the landscape.

D-C.6.8 Alternative D vs. F2050 (Revised)

Assessment of the Effects of Proposed Water Regimes Alternative D versus F2050 (Revised) on Snail Kites in South Florida

D-C.6.8.1 6Index Results

Figure FDSKMYFR.PDF shows the 31-year (1965-1995) average values of Snail Kite Indices (SKI) for foraging conditions across the model area. As indicated in the central panel of this set of three maps, Alternative D produces average SKI values slightly higher than or equivalent to those of F2050 (indicated by gold and gray colors in the central panel of Fig. FDSKMYFR.PDF) for nearly all of WCA-1, the southern half of WCA-2B, the northern half of WCA-3B and a large part of WCA-3A (south). F2050 results in higher SKI values for northern WCA-3A, the southern half of WCA-3B and the larger sloughs of Everglades National Park. WCA-2A shows great spatial variation in which scenario has a higher SKI value, with higher values under F2050 dominating at the downstream edge of the area.

The long-term average discussed above masks divergent effects of hydrologic conditions for individual years. During a "typical" year (1977, Fig. FDSK77FR.PDF) the spatial extent of foraging conditions suitable for Kite breeding is greatly reduced under both scenarios. There is no overlap in the spatial distribution of SKI values produced by F2050 and Alternative D. Alternative D provides scattered SKI values in southern WCA-1, WCA-3B, Northeast Shark Slough and Shark River Slough. F2050 produces SKI values in southern WCA-2B, western WCA-2A, sparsely in northern WCA-3A and the Holey Land WMA.

In the dry year of 1990 (Fig. FDSK90FR.PDF), foraging conditions suitable for breeding are practically non-existent across the model area under both F2050 and Alternative D. F2050 does provide a small area of intermediate SKI values in the Holey Lands WMA, but the overall difference between the two scenarios is negligible.

During a high rainfall year (1969, Fig. FDSK69FR.PDF, which was not an exceptionally high water year), there are spatial differences in SKI between the two scenarios. Alternative D produces equivalent or higher SKI values over all available foraging habitat in WCA-1, northern WCA-2A, southern WCA-2B, most of WCA-3A (south) and northwestern WCA-3B, relative to F2050. F2050 produces higher SKI values over southern WCA-2A and northern WCA-3A as well as part of the Holey Lands WMA. In Everglades National Park, central Shark River Slough has higher SKI values under F2050, while in the periphery of the Slough Alternative D produces higher SKI's.

During a high surface water year (1970, Fig. FDSK70FR.PDF), the distribution of SKI values and the differences between the scenarios is similar to the conditions described above. Under high surface water conditions, however, SKI values are higher under F2050, diminishing the magnitude of the differences between the scenarios. At even higher surface water conditions (1983, Fig. FDSK83FR.PDF), SKI values under both scenarios are lower than those predicted for 1970. Under these conditions F2050 produces higher SKI values for most of WCA-1, western and northern WCA-3A, southern WCA-3B, Northeast Shark River Slough, Shark River Slough and East Slough, relative to Alternative D. Alternative D produces equivalent or higher SKI values, relative to F2050, in the remaining habitat and expands into the fringes around Shark Slough and the WCA's.

During extremely wet years (Fig. FDSK95FR.PDF), SKI values are high across a large proportion of the landscape under both scenarios. However, under Alternative D, water levels are too high in parts of each of the WCA's, limiting the availability of snails to Kites. F2050, therefore, produces higher SKI values for much of the model area relative to Alternative D, although there are considerable spatial variations.

Figures FDSKT1FR.PDF and FDSKT2FR.PDF are temporal plots of total foraging potential realized for each of the WCA's and the mean across these selected subregions. Generally, both F2050 and Alternative D show the same trajectory over time, increasing and decreasing in step with index values falling below threshold levels proposed for successful breeding in most drought years. For WCA-1 and WCA-2A, Alternative D realizes a larger proportion of potential relative to F2050 in most years, except under very high water conditions. There is no clear pattern in the potential realized under the two scenarios for WCA-2B. For WCA-3A and B, Alternative D again realizes more potential than F2050 most years. Taken together, Alternative D out-performs F2050 in potential realized, especially in the early years of the model (FDSKT2FR.PDF: bottom).

D-C.6.8.2 Conclusion

Overall, Alternative D produces higher Snail Kite SKI's under a wide range of hydrologic conditions across all regions relative to F2050, often showing a faster recovery from drought conditions. As water depth increases, however, F2050 provides higher SKI values over a large part of the landscape.

D-C.7 CAPE SABLE SEASIDE SPARROW BREEDING POTENTIAL INDEX MODEL

ATLSS
Cape Sable Seaside Sparrow
Breeding Potential Index Model
Basic Model Description

John L. Curnutt, M. Philip Nott and Jane Comiskey
The Institute for Environmental Modeling
University of Tennessee, Knoxville
Knoxville, TN 37996-1610

D-C.7.1 Introduction

As part of the Central and Southern Florida Comprehensive Study Review (Restudy) several future water management regimes have been proposed. Each of these scenarios will affect potential breeding activity of the Cape Sable seaside sparrow (*Ammodramus maritimus mirabilis*) disproportionately across its range.

The model considers each of three distinct drainage basin zones currently containing known sub-populations of the sparrow.

The model briefly describes these in order of importance relative to current total population level of the sparrow. The first of these areas includes the core of the sparrow's range and lies within the Long Pine Key / South Taylor Slough drainage basin (Ingraham Highway area). Effects on this sub-population will be most significant to the population as a whole. Secondly, the westernmost sub-population occupies the East Slough drainage basin adjacent to the western edge of Shark's slough below Tamiami trail. This sub-population has been most affected by changes in water delivery since 1992, which restricted breeding activity and also resulted in drastic changes in vegetation patterns (Nott et al. in press). Finally, we consider the peripheral and highly fragmented sub-population within North Taylor Slough (and the southern portion of Northeast Shark Slough), that comprises only a small percentage of the total population.

The model express the effects of proposed scenarios as changes in the spatial pattern of breeding potential with reference to these three drainage basins with separate sub-populations. For brevity's sake we refer to them as the core, western and eastern areas, respectively.

D-C.7.2 Methods

The model estimates a sparrow breeding potential index (BPI) for those landscape cells which have the appropriate habitat type (Muhlenbergia dominated prairie) or on which sparrows have been observed to nest. The sparrow BPI model is driven by input data from the South Florida Water Management Model (SFWMM). These data, which are provided as daily water depths for each 2 x 2 mile area in the region covered by the model, are processed by the ATLSS landscape model into finer resolution hydrology. Water depths at the 500-m scale of resolution for ATLSS index models are based on a pseudo-topographic map, which incorporates information from a 28.5-meter resolution vegetation map (see high resolution hydrology and pseudotopography for a more detailed description (HYDRO___.DOC)).

The sparrow BPI reflects the duration and spatial extent of the annual dry season during which the water level in any cell remains below the nesting threshold level of 16cm. Computation of the BPI is based on knowledge of how hydrologic factors affect sparrow breeding success, including critical water level thresholds for each stage of the breeding cycle. The model uses water depth estimates to make spatially explicit predictions of the number of potential breeding cycles for each landscape cell. Each cell will have 0, 1, or 2 complete (45-day) cycles per breeding season.

A sparrow breeding cycle consists of a period of exploration/mating (10 days for first cycle, 5 days for subsequent cycles), nest building, egg laying, incubation of eggs, hatching, nestling stage, walking stage, and fledgling stage. For sparrows to raise young successfully, a window of 45 successive dry days between January 1 and June 30 is required for the fledglings to reach the walking stage. If a cycle is interrupted by rising water levels before the walking stage, we assume breeding was unsuccessful and the nestlings die. A new cycle begins with the next dry day.

The model overlays the computed brood cycle grid with a habitat-type map, utilizing known habitat preferences for sparrow colonization to compute breeding potential indexes from cell by cell brood cycle counts. Sparrows nest on landscape cells of short hydroperiod marl prairie characterized by dense stands of graminoid species (typically Muhlenbergia), usually below 1-m in height, uninterrupted by higher vegetation (trees or shrubs that would give potential predators a perch from which to survey the nesting area.). The vegetation map used is the April 1996 version of The Nature Conservancy (TNC) vegetation map. When selecting Muhlenbergia-dominated cells, we exclude those 500-m resolution cells with lower than 15% overall Muhlenbergia content, as determined by the proportion of constituent 28.5-m resolution cells categorized as Muhlenbergia (type 33) in the TNC map. In addition we include only those cells which are elements of appropriately sized larger clusters of Muhlenbergia cells. Breeding potential values for each cell are weighted by the higher of two values: the proportion of Muhlenbergia in that cell or a weighting factor reflecting the number of sparrows observed nesting and how recently birds were observed there.

Using BPI estimates for cells with preferred habitat in each drainage basin, the model plots time series graphs showing the percentage of available habitat in which successful breeding occurred over the 31-year period for which SFWMM simulated hydrology is available. Three-panel maps are used to show spatial comparisons between breeding potential for two scenarios and display the differences between them. The model presents maps, which represent 31-year averages, and also construct comparisons for selected years (i.e. high, low and average rainfall years as well as other years showing significant trends).

It is important to note that the sparrow BPI reflects the effect of hydrologic conditions for individual years. Obviously, sequences of bad years will have more serious effects than bad years interspersed among a number of good years. In the latter case the population may recover during the drier years. Some compensation for effects of successive dry years is provided in the BPI by computing a multiplicative weighting factor, which represents the mean over previous simulation years of a term reflecting short and long hydroperiod effects for each cell.

Estimates of scenario effects on the temporal patterns of population size require use of the individual based demographic model currently being developed.

As the duration of wet year sequences within any scenario approaches the maximum life span of the sparrow, the probability of local extinction increases.

Output associated with the ATLSS Cape Sable Seaside Sparrow Breeding Potential Index Model.

In accordance with ATLSS file naming conventions, each file name will consist of the characters: UVXXYYZZ.EXT

"U" or "_" => the Base, typically F for the F2050 base or E for the C1995 base
"V" or "_" => the alternative scenario or base
"XX" => "BC" for the ATLSS Cape Sable Seaside Sparrow Breeding Potential Index Model
"YYZZ" => 4 character mnemonic, described below
"."
"EXT" = "PDF" or "TXT" or "DOC" => PDF, tabular text or documentation

ATLSS Cape Sable Seaside Sparrow Breeding Potential Index

1. Maps

Map outputs used to characterize results of the Cape Sable Seaside Sparrow Breeding Potential Index Model will consist of eight image files in PDF file format. Each map shows a "Set" of model results, comparing one SFWMM hydrologic scenario to another, following the conventions for ATLSS comparisons of two model runs. Each map has three panels. The left panel displays index values for either an alternative or base scenario; the right panel displays index values for a base scenario (e.g., the Future without Project Conditions Case, or F2050). The middle panel displays the cell-by-cell difference between index values for the two compared scenarios (e.g., ALT-A minus F2050).

Grid cells in the left and right panels are color-coded to represent the (positive) values of the displayed index, which range between 0 and 1. Cell colors in the center panel represent either positive (shades of gold) or negative (shades of blue) differences between index values displayed in the left panel and those in the right panel. Color keys are provided at the bottom of each map. Each map depicts the model area at either a Fine (500-meter x 500-meter) or Coarse (2-mile) scale of resolution.

For each of six selected years, images will provide a spatial display of index values for that year. In addition, an image file is provided for the mean of all simulated years. The selected years include years with high, low, and typical rainfall, and several additional years that serve to highlight differences between the compared scenarios.

The mnemonic characters are composed according to the convention:

"YY" = Last two digits of the year
"ZZ" = CR - Coarse (2 mile) resolution, FR - Fine (500 meter) resolution

Listing of ATLSS Cape Sable Seaside Sparrow map files:

File Name	Time Period
UVBC69ZZ.PDF	A High Rainfall Year (1969)
UVBC70ZZ.PDF	Highlight Scenarios (1970)
UVBC77ZZ.PDF	A Typical Rainfall Year (1977)
UVBC83ZZ.PDF	Highlight Scenarios (1983)
UVBC90ZZ.PDF	A Low Rainfall Year (1990)
UVBC95ZZ.PDF	Highlight Scenarios (1995)
UVBCMYZZ.PDF	Mean of All Years (1965->1995)

2. Time Series

Time series sets associated with the ATLSS Cape Sable Seaside Sparrow Breeding Potential Index will display breeding potential values for three applicable subregions only. These show percentage of available habitat in which successful breeding occurred for each year.

File Name	Description
UVBCTSZZ.PDF	Percentage of available habitat in which successful breeding occurred for each year in each of three subregions.

3. Histograms None.

4. Tables None.

D-C.7.3 F2050 (Revised) vs. C1995 (Revised)

Assessment of the effects of proposed water regimes C1995 (Revised) vs F2050 (Revised) upon the potential breeding success and population dynamics of the Cape Sable Seaside-Sparrow.

The interpretation of results for the C1995 vs. F2050 hydrologic scenario includes a discussion of the results of both the Breeding Potential Index (BPI) and the spatially-explicit individual-based model, SIMSPAR. The BPI model provides single year snapshots of the effects of hydrology on the availability of breeding habitat throughout the sparrow's range. SIMSPAR, while only covering the region encapsulating the western sparrow subpopulation (see SIMSPAR model description), has the advantage of showing cumulative effects of sequences of wet or dry years. In addition to these two models, we apply the results of SIMSPAR to a population viability analysis (PVA).

D-C.7.3.1 Breeding Potential Index Model

The C1995 scenario positively affects sparrow breeding potential relative to F2050 for nearly all sparrow habitat. This is true for wet years (FEBC69FR.PDF, FEBC70FR.PDF, FEBC83FR.PDF) and even for typical and dry years (FEBC77FR.PDF, FEBC90FR.PDF). For two small areas, Lower Taylor Slough and the "stairsteps" region along the border of Everglades National Park and southern Big Cypress, the F2050 produces slightly higher BPI values over most hydrologic conditions. The difference between the BPI values produced under the two scenarios is accentuated under high surface water conditions (FEBC69FR.PDF, FEBC70FR.PDF, FEBC83FR.PDF, FEBC95FR.PDF). At extremely high surface water conditions sparrow breeding is greatly diminished west of Shark River Slough under both scenarios, however, east of the slough C1995 produces very high BPI values relative to F2050 (FEBC95FR.PDF).

D-C.7.3.2 Individual-based Model - SIMSPAR

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates the population variability for the western sparrow breeding area. The results of the C1995 scenario are shown on FESPTRAJ.PDF along with those from F2050.

Both F2050 and C1995 lead to a persistent, although variable breeding population. Figure FESPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin at 308 birds (the initial population for the western area - see Model Description). After a similar increase from 1965 to 1966, the predicted breeding populations quickly diverge under the two scenarios with C1995 increasing to a mean (calculated over 20 repetitions) of 500 breeding individuals by 1969 while under F2050 the breeding population slightly declines until 1971. The predicted breeding population under C1995 remains higher than under F2050 throughout the remainder of the model run, significantly so until 1980. Since the two scenarios produce the same trajectory over the model period the higher predicted populations under C1995 may be the result of the more favorable breeding conditions in the first three years under C1995. After the initial increase in breeding populations, both scenarios produce two peaks in predicted numbers (1978/1979 and 1991/1992) and one trough (1984/1985). Of these extreme breeding populations only the peak of 1978/1979 shows significant differences between the two scenarios with C1995 producing a mean breeding population of about 1800 individuals and F2050 producing 1100 individuals in 1979. The predicted breeding populations decline to 650 and 480 individuals under C1995 and F2050, respectively, in 1985. The populations then climb to 1950 and 1550 individuals under C1995 and F2050, respectively, in 1991/1992. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching just under 500 individuals in 1995 under both scenarios.

Figure FESPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV positively correspond with mean predicted breeding population (FESPMPOP.PDF). Suggesting that the stochastic nature of the model leads to higher variability with higher initial populations. Across all years, C1995 exhibits lower CVs than does F2050, never exceeding 0.15. Under F2050, after the fourth year the CV fluctuates between 0.15 and 0.3.

The fledgling productivity maps (FESPPROD.PDF) show that, averaging over all years, C1995 was more conducive to sparrow production than F2050 (FESPPROD.PDF: bottom). As discussed above, this initial difference in productivity (FESPPROD.PDF: top) resulted in higher predicted breeding populations under C1995 relative to F2050 for the first 15 model years. In 1994 (FESPPROD.PDF: middle), more fledgling were produced under F2050 relative to C1995 across the area studied. This was also the case in 1987 (not shown). For all other model years, C1995 produced more fledglings over more of the area than F2050. However, in ten years F2050 produced more fledglings in the northern one-third of occupied sparrow habitat.

D-C.7.3.3 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the model. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-")that the population will drop below a specified number over time. Under C1995, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the model period and a probability of 1.0 that it fall below 500 after two years (_ESPPTQX.PDF). Note that on this figure all of the lines are overlaid and only the last line (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF) there is a probability of 0.2 that the population will ever fall below 100 and a probability of 1.0 that the population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses F2050 shows an increasing probability of the population exceeding levels of up to 500 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching levels above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching levels above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under C1995 (_ESPPTQE.PDF), after 10 years the probability of reaching levels above 250 is 1.0 and above 500 is 0.9. After 25 years the probability of reaching levels above 1000 is 1.0 and above 2000 is 0.15. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the model. Under both scenarios (FESPPIER.PDF) the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 2000 breeding individuals is 0.5 under C1995 and 0.0 under F2050.

D-C.7.3.4 Conclusion

Under C1995 the sparrow breeding population reaches higher numbers early in the model years relative to F2050. This difference carries through until the final, high water years when the difference between the predicted breeding populations are insignificant. Overall, C1995 allows for higher fledgling productivity than F2050 and, partially as a consequence of this, C1995 breeding population estimates are less variable than those produced under F2050. The fledgling productivity maps show that, under either scenario, conditions are favorable enough for breeding sparrows to colonize nearly all available breeding habitat even though the model begins with the very constricted spatial distribution of breeding that we have witnessed in the recent high water years (compare FESPPROD.PDF top and middle).

D-C.7.4 Alternative A vs. F2050 (Revised)

Assessment of the effects of proposed water regimes Alternative A versus F2050 (Revised) upon the Potential Breeding Success and Population Dynamics of the Cape Sable Seaside-Sparrow.

As with the previous hydrologic scenario, the interpretation of results for Alternative A and F2050 includes a discussion of the results of both the Breeding Potential Index (BPI) and the spatially-explicit individual-based model, SIMSPAR. The BPI model provides single year snapshots of the predicted effects of hydrology on the availability of breeding habitat throughout the sparrow's range. SIMSPAR, while only covering the region encapsulating the western sparrow subpopulation (see SIMSPAR model description), has the advantage of showing cumulative effects of sequences of wet or dry years. In addition to these two models, we apply the results of SIMSPAR to a population viability analysis (PVA).

D-C.7.4.1 Breeding Potential Index Model

The F2050 scenario positively affects sparrow breeding potential relative to Alternative A for nearly all sparrow habitat east of Shark River Slough (FABCMYFR.PDF). This is true for wet years (FABC69FR.PDF, FABC70FR.PDF, FABC83FR.PDF) and even for typical and dry years (FABC77FR.PDF, FABC90FR.PDF). Indeed, F2050 produces higher BPI values east of Shark River Slough, relative to Alternative A, for every year in the simulation except 1965 (not shown), when BPI values for the two scenarios are equivalent. Generally, the magnitude of difference between the two scenarios east of the Slough is greatest under higher water conditions (FABC69FR.PDF, FABC83FR.PDF). In extremely high water years (FABC95FR.PDF), the spatial extent of suitable breeding conditions east of the Slough is greatly reduced.

For sparrow BPI values west of Shark River Slough, F2050 provides slightly higher values at the southern end of East Slough in 23 of the simulation years. This is seen in the 31-year mean (FABCMYFR.PDF) and, to varying degrees, in dry, "typical" and slightly higher water years (FABC90FR.PDF, FABC77FR.PDF, FABC69FR.PDF) but not in moderate to high water years (FABC70FR.PDF, FABC83FR.PDF, FABC95FR.PDF). For the remainder of potential sparrow breeding sites west of Shark River Slough, Alternative A provides higher BPI values, relative to F2050 (FABCMYFR.PDF). Under dry, "typical" and high rainfall conditions (FABC90FR.PDF, FABC77FR.PDF, FABC69FR.PDF), BPI values are only slightly higher under Alternative A, relative to F2050. In high to extremely high water conditions (FABC70FR.PDF, FABC83FR.PDF, FABC95FR.PDF), the differences are accentuated and Alternative A provides significantly higher BPI values, relative to F2050, for the area as a whole. This is partially due to the greater spatial extent of suitable breeding habitat west of Shark River Slough possible under Alternative A relative to F2050.

D-C.7.4.2 7Individual-based Model - SIMSPAR

SIMSPAR, unlike the breeding potential index model, provides a method of analyzing the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates population variability for the western sparrow breeding area. Results of the Alternative A scenario are shown in Fig. FASPTRAJ.PDF along with those from F2050.

Both F2050 and Alternative A lead to a persistent, although variable breeding population. Figure FASPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin with 308 birds (the initial population for the western area - see Model Description). Alternative A results consistently in significantly higher mean populations. The two predicted populations diverge after the first year of the simulation, and it may be this early difference that accounts for the subsequent higher populations under Alternative A. Both scenarios produce two peaks in predicted numbers (1979/1980 and 1991/1992) and one trough (1984/1985). Alternative A produces a mean breeding population of about 1600 individuals and F2050 produces 1100 individuals in 1978. Predicted breeding populations decline to 650 and 480 individuals under Alternative A and F2050, respectively, in 1985. The populations then climb to 2200 and 1550 individuals under Alternative A and F2050, respectively, in 1992. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 600 and 450 individuals for Alternative A and F2050, respectively, in 1995.

Figure FASPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV correlate positively with mean predicted breeding population (FASPMPOP.PDF), more so for F2050 than for Alternative A. After the first 4 years of the simulation, Alternative A exhibits lower CV's than does F2050. The lower CV's for Alternative A suggest that the ability of the population to reach higher numbers sooner, relative to F2050, allows for greater spatial distribution of breeders and, consequently, more stability in numbers between repetitions.

The fledgling productivity maps (FASPPROD.PDF) show that, averaging over all years, Alternative A is more conducive to sparrow production than F2050 (FASPPROD.PDF: bottom). In 1980 (FASPPROD.PDF: top), more fledglings were produced under F2050 relative to Alternative A across much the model area. This is the only year that F2050 produced more fledglings across the model area. In 14 other years, F2050 produced more fledglings in variously sized portions of the northern third of the model area. Even for these years, however, many more fledglings were produced under Alternative A over more of the model area than under F2050. In the extremely high water year of 1995 (FASPPROD.PDF: middle), Alternative A allows fledgling productivity over more of the study area, relative to F2050. Under both scenarios productivity is greatly reduced in 1995.

D-C.7.4.3 7Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the simulation. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative A, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the simulation period, a probability of 0.25 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after six years (_ASPPTQX.PDF). Note on this figure that all lines are overlaid and only the last line plotted (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF), there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that he population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses, F2050 shows an increasing probability of the breeding population exceeding levels of 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative A (_ASPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.9. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 1.0 that the population would reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FASPPIER.PDF), the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 1.0 under Alternative A and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 1.0 under Alternative A and 0 under F2050.

D-C.7.4.4 Conclusion

Relative differences between sparrow breeding population dynamics in the study area predicted under water regimes Alternative A and F2050 are significant, but complicated by the opposite effects that the scenarios have on sparrow breeding potential on either side of Shark River Slough. Generally, F2050 is more conducive to sparrow breeding east of the Slough and Alternative A is more conducive to breeding on the west side of the Slough. Since the BPI is not a quantitative measure, we are not able to determine the exact trade-off in predicted sparrow breeding given this spatially-based dichotomy. SIMSPAR is quantitative, and we show that the better breeding conditions west of the Slough under Alternative A relative to F2050 can lead to more sparrows. In the absence of a similar model for the area east of the Slough we are unable to determine which scenario is better for the global sparrow population.

An additional concern is that long-term habitat effects of conditions that are either too wet or too dry are difficult to assess with the BPI model. Specifically, long-term effects of dryness in the eastern area, which are difficult to measure, may counter-balance short-term effects of wet conditions, which are easily measured by counting days when water depths are above a threshold value for a given year. Hence, without a long-term vegetation change model, a scenario might be judged to be superior based on length of breeding season, when long-term changes in vegetative communities due to dryness under that water regime could lead to shrub invasion or changes in fire patterns. These, in turn, could have detrimental effects on sparrow breeding habitat.

D-C.7.5 Alternative B vs. F2050 (Revised)

Assessment of the effects of proposed water regimes Alternative B versus F2050 upon the Potential Breeding Success and Population Dynamics of the Cape Sable Seaside-Sparrow.

As with previous hydrologic scenarios, the interpretation of results for Alternative B and F2050 includes a discussion of the results of both the Breeding Potential Index (BPI) and the spatially-explicit individual-based model, SIMSPAR. The BPI model provides single year snapshots of the predicted effects of hydrology on the availability of breeding habitat throughout the sparrow's range. SIMSPAR, while only covering the region encapsulating the western sparrow subpopulation (see SIMSPAR model description), has the advantage of showing cumulative effects of sequences of wet or dry years. In addition to these two models, we apply the results of SIMSPAR to a population viability analysis (PVA).

D-C.7.5.1 Breeding Potential Index Model

The F2050 scenario positively affects sparrow breeding potential relative to Alternative B for nearly all sparrow habitat east of Shark River Slough (FBBCMYFR.PDF). This is true for wet years (FBBC69FR.PDF, FBBC70FR.PDF, FBBC83FR.PDF) and even for typical and dry years (FBBC77FR.PDF, FBBC90FR.PDF). Indeed, F2050 produces higher BPI values east of Shark River Slough, relative to Alternative B, for every year in the simulation except 1965 (not shown) when the values for the two scenarios are equivalent. Generally, the magnitude of the difference between the two scenarios east of the slough is greatest under higher water conditions (FBBC69FR.PDF, FBBC83FR.PDF). In extremely high water years (FBBC95FR.PDF), the spatial extent of suitable breeding conditions east of the slough is greatly reduced.

For sparrow BPI values west of Shark River Slough, F2050 provides slightly higher values at the southern end of East Slough in 18 of the simulation years. This is evident in the 31-year mean (FBBCMYFR.PDF) and, to varying degrees, in dry, "typical" and moderately high water years (FBBC90FR.PDF, FBBC77FR.PDF, FBBC69FR.PDF, FBBC70FR.PDF) but not in very high water years (FBBC83FR.PDF, FBBC95FR.PDF). For the remainder of potential sparrow breeding sites west of Shark River Slough, Alternative B provides higher BPI values, relative to F2050 (FBBCMYFR.PDF). Under dry, "typical" and high rainfall conditions (FBBC90FR.PDF, FBBC77FR.PDF, FBBC69FR.PDF), BPI values are only slightly higher under Alternative B, relative to F2050. In high to extremely high water conditions (FBBC83FR.PDF, FBBC95FR.PDF), the differences are accentuated and Alternative B provides significantly higher BPI values, relative to F2050, for the area as a whole. This is partially due to the greater spatial extent of suitable breeding habitat west of Shark River Slough possible under Alternative B relative to F2050.

D-C.7.5.2 Individual-based Model - SIMSPAR

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking into account the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates population variability for the western sparrow breeding area. Results of the Alternative B scenario are shown in Fig. FBSPTRAJ.PDF, along with those from F2050.

Both F2050 and Alternative B lead to a persistent, although variable, breeding population. Figure FBSPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin with 308 birds (the initial population for the western area - see Model Description). Alternative B results consistently in significantly higher mean populations. The two predicted populations diverge after the first year of the simulation and it may be this early difference that accounts for the subsequent higher populations under Alternative B. Both scenarios produce two peaks in predicted numbers (1979/1980 and 1991/1992) and one trough (1984/1985). Alternative B produces a mean breeding population of about 1550 individuals and F2050 produces 1100 individuals in 1978. Predicted breeding populations decline to 700 and 480 individuals under Alternative B and F2050, respectively, in 1985. The populations then climb to 2050 and 1550 individuals under Alternative B and F2050, respectively, in 1992. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 600 and 450 individuals for Alternative B and F2050, respectively, in 1995.

Figure FBSPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV correlate positively with mean predicted breeding population (FBSPMPOP.PDF), more so for F2050 than for Alternative B. After the first 6 years of the simulation, Alternative B exhibits lower CV's than does F2050. The lower CV's for Alternative B suggest that the ability of the population to reach higher numbers sooner, relative to F2050, allows for greater spatial distribution of breeders and, consequently, more stability in numbers between repetitions.

The fledgling productivity maps (FBSPPROD.PDF) show that, averaging over all years, Alternative B is more conducive to sparrow production than F2050 (FBSPPROD.PDF: bottom). In 1978 (FBSPPROD.PDF: top), more fledglings were produced under F2050 relative to Alternative B across much the model area. This occurred for the year 1987 and 1980 as well (not shown). In six other years, F2050 produced more fledglings in only the northern part of the model area. For all other simulation years, more fledglings were produced under Alternative B over more of the model area than under F2050. In the extremely high water year of 1995 (FBSPPROD.PDF: middle), Alternative B allows fledgling productivity over more of the study area, relative to F2050. However, under both scenarios productivity is greatly reduced in 1995.

D-C.7.5.3 7Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the simulation. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative B, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the simulation period, a probability of 0.6 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after six years (_BSPPTQX.PDF). Note on this figure that all lines are overlaid and only the last line plotted (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF), there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that the population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses, F2050 shows an increasing probability of the breeding population exceeding levels of 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative B (_BSPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.5. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 0.75 that the population will reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FBSPPIER.PDF), the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 1.0 under Alternative B and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 0.75 under Alternative B and 0 under F2050.

D-C.7.5.4 7Conclusion

Relative differences between sparrow breeding population dynamics in the study area predicted under water regimes Alternative B and F2050 are significant, but complicated by the opposite effects that the scenarios have on sparrow breeding potential on either side of Shark River Slough. Generally, F2050 is more conducive to sparrow breeding east of the slough and Alternative B is more conducive to breeding on the west side of the slough. Since the BPI is not a quantitative measure we are not able to determine the exact trade-off in predicted sparrow breeding given this spatially based dichotomy. The SIMSPAR model is quantitative, and shows that the better breeding conditions west of the slough under Alternative B relative to F2050 can lead to more sparrows. In the absence of a similar model for the area east of the slough we are unable to determine which scenario is better for the global sparrow population.

An additional concern is that long-term habitat effects of conditions that are either too wet or too dry are difficult to assess with the BPI model. Specifically, long-term effects of dryness in the eastern area, which are difficult to measure, may counter-balance short-term effects of wet conditions, which are easily measured by counting days when water depths are above a threshhold value for a given year. Hence, without a long-term vegetation change model, a scenario might be judged to be superior based on length of breeding season, when long-term changes in vegetative communities due to dryness under that water regime could lead to shrub invasion or changes in fire patterns. These, in turn, could have detrimental effects on sparrow breeding habitat.

D-C.7.6 Alternative C vs. F2050 (Revised)

Assessment of the effects of proposed water regimes Alternative C versus F2050 (Revised) upon the Potential Breeding Success and Population Dynamics of the Cape Sable Seaside-Sparrow.

As with previous hydrologic scenario, the interpretation of results for Alternative C and F2050 includes a discussion of the results of both the Breeding Potential Index (BPI) and the spatially-explicit individual-based model, SIMSPAR. The BPI model provides single year snapshots of the predicted effects of hydrology on the availability of breeding habitat throughout the sparrow's range. SIMSPAR, while only covering the region encapsulating the western sparrow subpopulation (see SIMSPAR model description), has the advantage of showing cumulative effects of sequences of wet or dry years. In addition to these two models, we apply the results of SIMSPAR to a population viability analysis (PVA).

D-C.7.6.1 Breeding Potential Index Model

The F2050 scenario positively affects sparrow breeding potential relative to Alternative C for nearly all sparrow habitat east of Shark River Slough (FCBCMYFR.PDF). This is true for wet years (FCBC69FR.PDF, FCBC70FR.PDF, FCBC83FR.PDF) and even for typical and dry years (FCBC77FR.PDF, FCBC90FR.PDF). In moderately dry (1972 through 1976, not shown) and, to some extent, in typical years (FCBC77FR.PDF), Alternative C provides higher BPI values just east of Shark River Slough proper and in the southern marl prairies east of the Slough. For all but very high surface water conditions (FCBC70FR.PDF, FCBC83FR.PDF, FCBC95FR.PDF), when sparrow breeding is precluded under both scenarios, F2050 provides higher BPI values relative to Alternative C for the southern end of East Slough. For the remainder of the sparrow's potential breeding habitat west of Shark River Slough, Alternative C produces higher BPI values relative to F2050. This is true for all conditions (FCBC90FR.PDF, FCBC77FR.PDF, FCBC83FR.PDF, FCBC69FR.PDF, FCBC70FR.PDF, FCBC95FR.PDF), and is accentuated under very high surface water conditions (FCBC70FR.PDF, FCBC83FR.PDF, FCBC95FR.PDF), when breeding is more curtailed under F2050 relative to Alternative C.

D-C.7.6.2 7Individual-based Model - SIMSPAR

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates population variability for the western sparrow breeding area. Results of the Alternative C scenario are shown in Fig. FCSPTRAJ.PDF along with those from F2050.

Both F2050 and Alternative C lead to a persistent, although variable breeding population. Figure FCSPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin with 308 birds (the initial population for the western area - see Model Description). Predicted breeding populations under the two scenarios are very similar through time. Alternative C results in significantly higher mean populations only from 1967 through 1977. Both scenarios produce two peaks in predicted numbers (1978/1979 and 1991/1992) and one trough (1984/1985). Alternative C produces a mean breeding population of about 1400 individuals and F2050 produces 1100 individuals in 1978. Predicted breeding populations decline to 500 and 480 individuals under Alternative C and F2050, respectively, in 1985. The populations then climb to 1750 and 1550 individuals under Alternative C and F2050, respectively, in 1992. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 500 individuals in 1995 under both scenarios.

Figure FCSPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV correlate positively with mean predicted breeding population (FCSPMPOP.PDF). Through the 1970's and through the 1990's, Alternative C exhibits lower CV's than does F2050. Although the CV's of both scenarios are similar, the lower values in the crucial wet years of 1992 - 1995 for Alternative C suggest that the breeding population has more of a chance of persisting through extreme conditions under this scenario relative to F2050.

The fledgling productivity maps (FCSPPROD.PDF) show that, averaging over all years, Alternative C is more conducive to sparrow production than F2050 (FCSPPROD.PDF: bottom). In 1980 (FCSPPROD.PDF: top), more fledglings were produced under F2050 relative to Alternative C across the area studied. This was also the case in 1978, 1980, 1987, and 1992 (not shown). For all other model years, more fledglings were produced under Alternative C over more of the model area than under F2050. However, for eight of these years (not shown) more fledglings were produced under F2050 in parts of the model area. In the extremely high water year of 1995 (FCSPPROD.PDF: middle), Alternative C allows fledgling productivity over more of the study area, relative to F2050. However, under both scenarios productivity is greatly reduced in 1995.

D-C.7.6.3 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the model. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative C, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the model period, a probability of 0.9 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after one year (_CSPPTQX.PDF). Note on this figure that all lines are overlaid and only the last line plotted (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF), there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that the population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses, F2050 shows an increasing probability of the breeding population exceeding levels of 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative C (_CSPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.45. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 0.05 that the population would reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FCSPPIER.PDF), the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 0.95 under Alternative C and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 0.10 under Alternative C and 0 under F2050.

D-C.7.6.4 Conclusion

Relative differences between sparrow breeding population dynamics in the study area predicted under water regimes Alternative C and F2050 are minor. Alternative C appears to be more conducive to breeding population recovery after a decline relative to F2050. This is apparent in the fledgling productivity maps and the PVA results.

D-C.7.7 Alternative D vs. F2050 (Revised)

Assessment of the effects of proposed water regimes Alternative D versus F2050 (Revised) upon the potential breeding success and population dynamics of the Cape Sable Seaside-Sparrow.

As with previous hydrologic scenario, the interpretation of results for Alternative D and F2050 includes a discussion of the results of both the Breeding Potential Index (BPI) and the spatially-explicit individual-based model, SIMSPAR. The BPI model provides single year snapshots of the predicted effects of hydrology on the availability of breeding habitat throughout the sparrow's range. SIMSPAR, while only covering the region encapsulating the western sparrow subpopulation (see SIMSPAR model description), has the advantage of showing cumulative effects of sequences of wet or dry years. In addition to these two models, we apply the results of SIMSPAR to a population viability analysis (PVA).

D-C.7.7.1 Breeding Potential Index Model

The F2050 scenario positively affects sparrow breeding potential relative to Alternative D for nearly all sparrow habitat east of Shark River Slough (FDBCMYFR.PDF). This is true for wet years (FDBC69FR.PDF, FDBC70FR.PDF, FDBC83FR.PDF) and even for typical and dry years (FDBC77FR.PDF, FDBC90FR.PDF). F2050 also provides higher BPI values relative to Alternative D for the "stairstep" region of Big Cypress and Everglades National Park and for the prairies just west of Shark River Slough. In the former area under all hydrologic conditions and in the latter area under all but extreme high water conditions. Under both scenarios, during extreme high water years (FDBC83FR.PDF, FDBC95FR.PDF) the spatial extent of sparrow breeding habitat is greatly reduced, especially west of Shark River Slough.

Alternative D produces higher BPI values relative to F2050 for the area in and around East Slough during dry, "typical", and high rainfall conditions (FDBC90FR.PDF, FDBC77FR.PDF, FDBC83FR.PDF). During extreme high water years, breeding is precluded in and around East Slough (FDBC69FR.PDF). Under these conditions Alternative D provides for some restricted breeding potential, but neither scenario provides significant amounts of breeding habitat.

D-C.7.7.2 Individual-based Model - SIMSPAR

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates population variability for the western sparrow breeding area. Results of the Alternative D scenario are shown in Fig. FDSPTRAJ.PDF along with those from F2050.

Both F2050 and Alternative D lead to a persistent, although variable breeding population. Figure FDSPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin with 308 birds (the initial population for the western area - see Model Description). Predicted breeding populations under the two scenarios are very similar through time. Alternative D results in significantly higher mean populations only from 1973 through 1977. Both scenarios produce two peaks in predicted numbers (1978/1979 and 1991/1992) and one trough (1984/1985). Alternative D produces a mean breeding population of about 1400 individuals and F2050 produces 1100 individuals in 1978. Predicted breeding populations decline to 600 and 480 individuals under Alternative D and F2050, respectively, in 1985. The populations then climb to 1750 and 1550 individuals under Alternative D and F2050, respectively, in 1991. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 500 individuals in 1995 under both scenarios.

Figure FDSPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV positively correspond with mean predicted breeding population (FDSPMPOP.PDF). From 1975 onwards, Alternative D exhibits lower CV's than does F2050, never exceeding 0.20. Under F2050, after the fourth year the CV fluctuates between 0.15 and 0.3.

The fledgling productivity maps (FDSPPROD.PDF) show that, averaging over all years, Alternative D is more conducive to sparrow production than F2050 (FDSPPROD.PDF: bottom). In 1980 (FDSPPROD.PDF: top), more fledglings were produced under F2050 relative to Alternative D across the area studied. This was also the case in 1978 and 1987 (not shown). For all other model years, more fledglings were produced over more of the model area under Alternative D than under F2050. However, for nine of these years (not shown) more fledglings were produced in portions of the model area under F2050. In the extremely high water year of 1995, higher fledgling productivity is seen under Alternative D (FDSPPROD.PDF: middle).

D-C.7.7.3 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the model. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative D, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the model period, a probability of 0.8 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after one year (_DSPPTQX.PDF). Note on this figure that all lines are overlaid and only the last line plotted (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF), there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that the population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses, F2050 shows an increasing probability of the breeding population exceeding levels of 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative D (_DSPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.3. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 0.15 that the population would reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FDSPPIER.PDF), the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 0.95 under Alternative D and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 0.10 under Alternative D and 0 under F2050.

D-C.7.7.4 Conclusion

Relative differences between sparrow breeding population dynamics in the study area predicted under water regimes Alternative D and F2050 are minor. Alternative D appears to be more conducive to breeding population recovery after a decline relative to F2050. This is apparent in the fledgling productivity maps and the PVA results.

D-C.7.8 Alternative D13R vs. F2050 (Revised)

Assessment of the effects of proposed water regimes Alternative D13R versus F2050 (Revised) upon the Potential Breeding Success and Population Dynamics of the Cape Sable Seaside-Sparrow

As with previous hydrologic scenario, the interpretation of results for Alternative D13R and F2050 includes a discussion of the results of both the CSSS Breeding Potential Index (BPI) and the spatially-explicit individual-based model, SIMSPAR. The BPI model provides single year snapshots of the effects of hydrology on the availability of breeding habitat throughout the sparrow's range. SIMSPAR, while only covering the region encapsulating the western sparrow subpopulation (see SIMSPAR model description), has the advantage of showing cumulative effects of sequences of wet or dry years. In addition to these two models, we apply the results of SIMSPAR to a population viability analysis (PVA). In all figure legends Alternative D13R is referred to as Alt G - this is in keeping with our alphanumeric code for labeling figures.

D-C.7.8.1 Breeding Potential Index Model

The F2050 scenario positively affects sparrow breeding potential relative to Alternative D13R for sparrow habitats east of Shark River Slough (FGBCMYFR.PDF) under most hydrologic conditions. The magnitude of the difference in BPI values is greatest in wet years (FGBC69FR.PDF, FGBC70FR.PDF, FGBC83FR.PDF) and least for typical and dry years (FGBC77FR.PDF, FGBC90FR.PDF). F2050 also provides higher BPI values relative to Alternative D13R for the southern portion of the western sparrow breeding area under all but the wettest hydrologic conditions. Alternative D13R provides higher BPI values relative to F2050 in the northern portion of the western breeding area. Under both scenarios, during extreme high water years the spatial extent of sparrow breeding habitat is greatly reduced, especially west of Shark River Slough.

D-C.7.8.2 Individual-based Model - SIMSPAR

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates the population variability for the western sparrow breeding area. Results of the Alternative D13R scenario are shown on FGSPTRAJ.PDF, along with those from F2050.

Both F2050 and Alternative D13R lead to a persistent, although variable breeding population. Figure FGSPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin at 308 birds (the initial population for the western area - see Model Description). The predicted breeding populations under the two scenarios are very similar through time. Alternative D13R results in significantly higher mean populations only from 1967 through 1970 and from 1972 through 1977. Both scenarios produce two peaks in predicted numbers (1978/1979 and 1991/1992) and one trough (1984/1985). Alternative D13R produces a mean breeding population of about 1400 individuals and F2050 producing 1100 individuals in 1978. The predicted breeding populations decline to 600 and 480 individuals under Alternative D13R and F2050, respectively, in 1985. The populations then climb to 1750 and 1550 individuals under Alternative D13R and F2050, respectively, in 1991. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 500 individuals in 1995 under both scenarios.

Figure FGSPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV positively correspond with mean predicted breeding population (FGSPMPOP.PDF). From 1975 onwards, Alternative D13R exhibits lower CV's than does F2050, never exceeding 0.20. Under F2050, after the fourth year the CV fluctuates between 0.15 and 0.3.

The fledgling productivity maps (FGSPPROD.PDF) show that, averaging over all years, Alternative D13R was more conducive to sparrow production than F2050 (FGSPPROD.PDF: bottom). In 1980 (FGSPPROD.PDF: top), more fledgling were produced under F2050 relative to Alternative D13R across the area studied. This was also the case in 1978 and 1987 (not shown). For all other simulation years, Alternative D13R produced more fledglings over more of the area than F2050 did. However, for nine of these years (not shown) F2050 produced more fledglings in parts of the model area. In the extremely high water year of 1995, Alternative D13R allows higher fledgling productivity (FGSPPROD.PDF: middle).

D-C.7.8.3 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the simulation. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative D13R, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the simulation period, a probability of 0.9 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after one year (_GSPPTQX.PDF). Note that on this figure all of the lines are overlaid and only the last line (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF) there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that it will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses F2050 shows an increasing probability of the breeding population exceeding levels of up to 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative D13R (_GSPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.2. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 0.2 that the population would reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FGSPPIER.PDF) the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 1.0 under Alternative D13R and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 0.2 under Alternative D13R and 0 under F2050.

D-C.7.8.4 Conclusion

Alternative D13R produces lower BPI values relative to F2050 in the eastern sparrow breeding area and in the southern portion of the western breeding area under most hydrologic conditions. The results of SIMSPAR suggest that the sparrow population can reach higher levels more often under Alternative D13R, relative to F2050. Alternative D13R also produces a more stable sparrow population and it appears to be more conducive to breeding population recovery after a decline relative to F2050. This is apparent in the fledgling productivity maps and the PVA results.

D-C.8 INDIVIDUAL-BASED MODEL - SIMSPAR

SIMSPAR

Version 1.3

A Spatially-explicit Individual-based Object-oriented Simulation Model for the Cape Sable seaside sparrow in the Everglades and Big Cypress Landscapes

Philip Nott, Jane Comiskey, John Curnutt and Louis Gross
The Institute for Environmental Modeling
Tennessee Knoxville, TN 37996-1610

D-C.8.1 Introduction

The Cape Sable seaside sparrow (*Ammodramus maritimus mirabilis*) is an ecologically isolated subspecies of the seaside sparrow (Beecher 1955). Recent surveys estimate a population size of approximately 3000 individuals (from 6000+ in 1992), and its range is restricted to the extreme southern portion of the Florida peninsula, almost entirely within the boundaries of the Everglades National Park and Big Cypress National Preserve (Werner 1975, Bass and Kushlan 1982). The sparrow currently breeds in marl prairies typified by dense stands of graminoid species usually below 1m in height and naturally inundated by freshwater during part of the year. As water levels recede during the dry season in late winter and spring, the sparrows establish territories and start nesting in dense grass tussocks. Several broods may result from a single male territory if hydrologic conditions allow (Lockwood et al. 1997). If water levels do not recede early enough in spring, nesting may be delayed, and if water levels subsequently rise during the nesting season, eggs or nestlings may be drowned. Recent declines have occurred in the sparrow population across its entire range, probably due to higher water levels in recent years (Pimm et al. 1995). Because the current range of the sparrow is limited to a few hundred square kilometers and because it is subject to flooding and fires, the population is highly vulnerable. The Everglades restoration project (Hinrichson 1995) plans to change the hydrology of the southern Everglades. Changing water levels in parts of the sparrow's range would affect the reproductive success of the sparrow. This model attempts to quantify the relative impact of alternative hydrologic regimes on the survival of sparrow populations.

D-C.8.2 SIMSPAR Version 1.3

Several important features are supported in Version 1.3. Significantly, the ATLSS habitat layer (TNC GAP analysis) is spatially integrated with the existing topology and with extensive sparrow survey data. Subsequent analysis provides a set of rules with which to define potential breeding habitat. SIMSPAR predicts population levels and spatial distributions of breeding activity that correlate well with field data.

D-C.8.3 SIMSPAR landscape

The landscape of the sparrow's range is modeled explicitly as a set of spatial cells of fine enough resolution (500m) to represent areas of similar vegetation, topography, and hydrology. The spatial extent of the model is an area west of Shark River Slough covering 18 x 28.5 km. In this implementation of SIMSPAR only the western subpopulation is included, since it is the only region for which field estimates of fine resolution topography are available. SIMSPAR is capable of being applied to other subpopulations when these topographic data become available.

1. Universal Transverse Mercator coordinates describe the spatial extent of the area modeled, which encapsulates the western sub-population (UTM Zone 17: Northing 2 851 070, Southing 2 821 570, Easting 517 665, Westing 499 665). This area is expressed as a 500m-resolution landscape (59 rows x 36 columns) and corresponds geographically to the top left-hand box shown in SPARLAND.PDF. The symbols within this box mark the historical locations of breeding sparrows determined from extensive surveys in 1981, and every year since 1992 (Curnutt et al. 1998).

2. This portion of the 1994 TNC habitat map overlays the topography previously derived from water depth measurements made during the 1995 extensive sparrow survey. Interpolating non-uniformly spaced estimates of elevation using an inverse distance method creates this topography.

3. We determined from the fine-scale 30m-resolution TNC habitat map, the percentage cover of each habitat type within each 500m resolution cell. This is represented by a false color image of the area shown in WESTTNCH.PDF, black lines delineate the boundaries of each 500m cell considered. A key to the 25 commonest (by % cover) classes depicted in this image is given in WESTTNCK.PDF.

4. We analyzed the fine scale habitat data associated with the 79 known locations of breeding sparrows observed in the 1992 extensive sparrow survey (Nott in prep.). Sonny Bass of Everglades National Park conducted this survey. The results of these analyses are summarized as a set of 41 habitat type tolerances and 2 habitat preference rules, tabulated in TNCRULES.TXT and described briefly below.

* The 41 individual habitat types do not cover more than a certain percentage of any 500m-resolution cell in which breeding sparrows were observed in 1992.

* The majority (76) of the 79 known 1992 breeding locations contain greater than 70% coverage of habitat types 30,33, and 39.

* Only 4 of the 79 known 1992 breeding locations are associated with less than 30% coverage of 'wetter' marshland habitat types (0 23 24 25 29 31 32 34 38 40 41).

* The Cape Sable Seaside-Sparrow is known to avoid trees when establishing breeding territories. Many trees exist across the western landscape that are sub-30m resolution features and therefore do not appear in the TNC habitat map. We complemented the TNC map by determining the locations of tree infested survey sites from the 1992 extensive survey data. The trees Bass observed at these sites include pine, hardwood, cypress, willow and mangrove.

5. The results of these analyses are summarized in WESTLAND.PDF. Cells which do not meet the criteria set in the first three rules are marked as non-habitat cells and are shown as diagonal crosses (x). The cells in which survey trees occurred are marked as non-habitat; with vertical crosses (+). Cells in which an asterix (*) appears are cells defined as non-habitat by both the analysis of TNC data and the known locations of trees from extensive survey data.

The resultant landscape contains fewer cells available for breeding than version 1.0 in which the available habitat was simply defined by an upper limit of elevation. We might expect results to be more variable between simulations given the patchiness of available breeding habitat in version 1.3 to those of version 1.0 due to the effects of inherent stochastic processes on isolated pockets of breeding individuals.

D-C.8.4 Individual based approach

SIMSPAR provides continuous, spatially-explicit estimates of population size and structure by following the actions, growth, reproduction and mortality of each individual sparrow in the region. It follows the state of each individual sparrow including its sex, age, reproductive status and location. The model increases the age of an individual each day and updates its status according to movement and behavior rules. The backbone of the model is a simple flow of decisions and actions that affect individuals in relation to abiotic factors and other individuals. The model is stochastic in that there are probability distributions for each state change of an individual, thus requiring a set of Monte Carlo simulations for each scenario.

1. Each individual sparrow in the population is modeled during the breeding period. This may occur sometime between mid-February and as late as early August of each year, dependent upon hydrologic conditions. In particular, the model tracks the sex, age, breeding status, of each model individual from egg to the end of its life. For mature males, the model tracks establishment of breeding territories, finding a mate, the start of nesting, and the status of eggs and nestlings on a daily basis. The life cycle parameters used in the model are taken from life history studies of the sparrow (Werner 1975, Lockwood et al. 1997).

One important such parameter is that of annual adult survival rate. Pimm (pers. comm.) reports an analysis of banding data (A. m. mirabilis) suggesting a survival rate of 0.5. Post and Greenlaw's (1982) analysis of data for resident *Ammodramus maritimus maritimus* in New York salt marshes suggests 0.57-0.6. Both Werner (1975) and Post et al. (1983) suggest a value of 0.85 for territorial males, but both these studies used low sample numbers over a single year (N=16, N=21 respectively). A review by Martin and Li gives an average value of 0.55 for both sexes. This is based on a study by Nichols et al. (1981) of 112 permanent resident seaside sparrows over a 10 year period using the Jolly-Seber technique. SIMSPAR adopts an adult survival rate of 0.6.

2. The relationship of sparrow breeding activity to water depth is modeled. Water depth in spatial cells is tracked daily through a hydrologic model. A spatial cell is not available for breeding activity (specifically mating and nest building) until the water level in that cell falls below a threshold level of 5 cm. Any rise in the water level above 14 cm in a particular spatial cell during the nesting season is assumed to cause nest abandonment for sparrows that have nests in that cell. The elevation of a cell relative to the water stage determines the length of the effective reproductive season for the pair of sparrows and the vulnerability of the nest to flooding. The sparrows are not modeled in detail during the non-breeding season. Age-specific mortality rates are assigned during that period probabilistically, currently the age dependent mortality is set at 1.0 - 0.6 = 0.4 for all age classes.

3. At the beginning of each breeding season males that previously owned territories return to those nesting territories as do the females. Females may not remain in that cell during the breeding season, as females are relatively mobile and may range up to 4 kilometers to find a mate. Recruits return to a habitable location in the vicinity of their natal site. Dispersal occurs before the beginning of the breeding season, are dispersing individuals move stepwise across the landscape searching for suitable breeding habitat.

An individual chooses a cell in its 8-cell neighborhood with equal probability. An individual cannot move to a non-habitat cell (as per WESTLAND.PDF), or a cell it has previously visited but failed to occupy. This is defined as a 'self- avoiding random flight' henceforth known as SARF. This assumes the individual has gained a 'perfect knowledge' of the location and status of cells it previously visited. At each step an individual tests the cell to determine the availability of vacant territories. If a vacant territory exists, it will end its search and is assigned to that cell. If no vacant territories exist it will attempt to move again following the rules described above.

Individuals start their search in their natal cell and with each step there is a 0.1 probability of mortality. This simulates the danger of moving during which time they risk predation and starvation. If an individual encounters a cul-de-sac in which it cannot move to a cell it has not already visited it remains there as a floater. This process results in cells being saturated with males, a roughly equal number of females, and a number of 'floaters' able to occupy territories that become available due to the death of the male 'owner' or its mate. It also results in a number of individuals dispersing to adjacent potential breeding habitat where they can attempt to breed.

These rules have the effect that after a productive year in which many individuals fledged successfully the extent of the area occupied by sparrows increases. The distribution of dispersal distances reveals that most individuals disperse locally within 0-2 km, but a few may disperse as far as 5-6 km. After wet years recruits have a higher probability of ending their search in or close to their natal site thereby saturating previously productive cells. In this case dispersal is normally restricted to 0-2km.

Applying these rules to the validation run (using real NP205 stage height data 1981-1997) results in simulations that resemble the temporal and spatial pattern seen in the results of the extensive sparrow surveys of 1981,1992, and 1993-1997.

D-C.8.5 Model population initialization

The 'seed' population used in SIMSPAR Version 1.3 is both spatially and numerically explicit. It is based on extensive helicopter survey counts of singing males at the vertices of a 1km grid. Bass and Kushlan (1983) multiply the number of singing male sparrows by a factor of 16 to estimate the total number of birds within 1km2.

The seed SIMSPAR population distribution consists of a composite distribution of 1993, 1995, 1996 and 1997 sparrow observations, not just the 1997 distribution. We assume the extensive helicopter survey misses low levels of breeding activity at these historical locations, the so-called 'veil' effect. This same effect is observed in validation runs of SIMSPAR in which randomly chosen cells are sampled for the presence of singing males. No males are detected in some cells but breeding activity occurs at some time during the breeding season.

There are several possible reasons why breeding activity may be undetectable at a site (i.e. no males were singing). Either water conditions are unsuitable, the males are not singing while caring for walking fledglings or, singing males are too distant to be heard. In summary, the initial population is distributed among 5 main patches depicted by the white circles in SPARTOPO.PDF.

Determining the initial population size and distribution requires processing of the raw data. Firstly, because several years of data are combined to produce the initial distribution more singing males are present than are present in 1997 alone. Secondly, because the locations of breeding sparrows were surveyed at a 1km-resolution, these map out into every other 500m-resolution SIMSPAR cell. To deal with this problem we extrapolate each observation to fill the remaining 3 cells of a 2 x 2 cell block equivalent to 1km2 in area. We multiply the total number of birds per cell (given by the composite distribution above) by a factor of 16/(No. of 500m cells in 1km2) = 4, in accordance with the correction factor of Bass and Kushlan (1983). Finally, we halve this number to produce an initial population size of 308 birds.

D-C.8.6 Life cycle and behavioral parameters

The life cycle and behavioral parameter values used in the model produce population-level estimates close to the field estimates when the real NP205 hydrologic dataset (for the period 1977-1996) is used to drive the model. These values are documented in table F5SPARAM.TXT. Many of these remain the same as for Version 1.0 with a few notable exceptions:

The maximum allowable density of breeding territories per cell is set to 4, equivalent to a maximum of 16 breeding pairs per 1km2. This equates to 4 singing males recorded in the extensive survey. SIMSPAR assumes a uniform spatial distribution of the maximum density of breeding territories per cell. Observed densities vary between 1 and 16 but the relationship between territory density and habitat heterogeneity is not yet fully understood.

The onset of nesting activity is crucial to the number of broods a pair of sparrows may produce. The earliest recorded nesting activity occurred mid-March in both 1996 and 1997, despite the fact conditions were dry prior to that date (Lockwood pers. comm.). Therefore, SIMSPAR assumes an environmental trigger, probably photoperiod, is responsible for the onset of breeding. Accordingly, the SIMSPAR breeding cycle begins at the end of February and continues until the beginning of August. Given initially dry conditions, the peak of the first breeding cycle predicted by SIMSPAR occurs between mid-March and mid-April, similar to the peak of first brood activity observed in the field. During the SIMSPAR breeding cycle males may mate a maximum of three times given suitable short-hydroperiod conditions, and may successfully raise three broods.

D-C.8.7 Hydrology model

The model is driven by daily water level data from a single cell close to the sub-populations under study. Specifically, we designed and tested the model using historical data from a National Park Service hydrologic monitoring station. The western area is influenced by the hydrologic patterns experienced at the station NP205 located at (Northing 2825223 Easting 515235).

In light of the sensitivity of the model to variations in water depth, we have reevaluated our choice of the particular SFWMM 2-mile x 2-mile grid cell for representing water depth at Gage NP205. This gaging station lies near the juncture of 4 SFWM grid cells. After reviewing graphs of SFWMM calibration/validation depth values for these four cells, in comparison with historical gage data, we have chosen the cell, numbering from the upper left, in the 47th row and 16th column (which would be 46,15 if numbered from 0) to use for all comparisons in the upcoming evaluations. It is our understanding that ENP hydrologists use the 46th row and 16th column, which is our row 45 column 15 or, counting from lower left, starting from 1, their row 20, column 16), or in some cases the mean of values for the four cells.

D-C.8.8 Stochasticity

The model is initialized with a population of 308 sparrows reflecting the size of the 1997 population estimate for this region (Curnutt et al. 1998). The individuals are placed in higher elevation cells but not at ones for which trees and shrubs dominate the vegetation, concordant with the findings of Nott et al. (1998). The initial locations do not vary among replicates. A number of replicate simulations (typically 20) are run for each hydrologic scenario. Each replicate employs a different random number seed which causes variability in the temporal and spatial patterns of successful breeding. The "variability" incorporated in this model affects individuals' breeding locations, mate choice, mating success, clutch size, gender, dispersal and mortality. Due to this individual-level stochasticity, population- level estimates from the model vary among replicates. This stochasticity allows for construction of a population viability analysis, in which estimates are made of the probability of population levels falling below or going above certain thresholds. These probabilities are calculated by determining what fraction of the replicate simulations cross these thresholds.

D-C.8.9 Population Viability Analysis (PVA)

All scenario comparisons are made using 3 distinct PVA techniques: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the model.

a) Time to quasi-extinction (TQX) is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time.

b) Time to quasi-explosion (TQE) is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time.

c) Interval explosion risk (IER) is the probability that the population will reach a certain number over the period of the model.

Acknowledgements

Phil Nott wishes to thank all parties who attended his presentation of this model on February 19th 1998 at the Center for Natural Resources in Everglades National Park, and at the meeting on April 24th at SFWMD headquarters in Palm Beach. Many invaluable comments and suggestions were made, some of which are included in this version.

Output associated with the ATLSS Individual-based Cape Sable Seaside Sparrow Model.

In accordance with ATLSS file naming conventions, each file name will consist of the characters:

"X" or "_" => the Base, typically F for the F2050 base or E for the C1995 base
"X" or "_" => the alternative scenario or base
"SP" => the ATLSS Individual-based Cape Sable Seaside Sparrow Model
"XXXX" => 4 character mnemonic
"."
"PDF" or "TXT" or "DOC" => PDF, tabular text or documentation

ATLSS Individual-based Cape Sable Seaside Sparrow

1. Maps

Map outputs used to characterize results of the Individual-based Cape Sable Seaside Sparrow component of ATLSS will consist of a number of image files in

PDF file format. A 30m-resolution habitat map of the western region is shown in WESTTNCH.PDF with its associated key WESTTNCK.PDF. A 500m-resolution map of the topology and associated non-habitat cells is shown in WESTLAND.PDF ,superimposed on this map are the locations of the initial population distribution.

SIMSPAR also outputs a "Set" of model results, comparing a Base case to a Scenario, following the conventions for ATLSS comparison of two model runs. The extent of the map is the western region of the Everglades as shown on the map "SPARLAND.PDF". Each map has 3 panels. The left panel is an alternative or base scenario. The right panel is the base scenario, typically the Future without Project Conditions Case. The middle panel is the difference between the two scenarios.

Each map depicts the model area at a fine (500-meter x 500-meter) scale of resolution, with each cell color coded to represent the annual productivity value or the difference between the annual productivity value in the alternative scenario and the base scenario. For more information on the productivity values, see the section on Visualization above.

For each of a list of years, the images will provide a spatial display of productivity values during that year. In addition, there is an image file for the mean of all simulated years. The list of years are those that serve to highlight the differences between the scenarios.

The mnemonic characters are composed according to the convention:

"XX" = Last two digits of the year
"XX" = PM - Productivity Map

An example of an ATLSS Individual-based Cape Sable Seaside Sparrow map file name. FASPMYPM.PDF - Comparison map displaying all years mean productivity of F2050 Base and the Alternative A scenario.

2. Time Series

Time series sets associated with the ATLSS Individual-based Cape Sable Seaside Sparrow will display replicate population trends, the variability of populations and population viability analyses. For information on population trends and variability, see the section on Visualization above. For information on population viability see the sections on Stochasticity and Visualization above.

File Name	Description
XXSPTRAJ.PDF	Shows a single line representing population trajectories for each replicate simulation and both a base and a scenario run.
XXSPCVAR.PDF	Summarizes the coefficient of variation in predicted population levels for both a base and a scenario run.
XXSPPTQX.PDF	Presents probabilities of time to quasi-extinction based upon replicates for either a base or scenario run.
XXSPPTQE.PDF	Presents probabilities of time to quasi-explosion based upon replicates for either a base or scenario run.
XXSPPIER.PDF	Presents interval explosion risk based upon replicates for both a base and a scenrio run.
XXSPMPOP.PDF	Presents the mean and standard deviation of the predicted breeding population size for both a base and a scenario run.

4. Tables None

D-C.8.10 F2050 (Revised) vs. C1995 (Revised)

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates the population variability for the western sparrow breeding area. The results of the C1995 scenario are shown on FESPTRAJ.PDF along with those from F2050.

Both F2050 and C1995 lead to a persistent, although variable breeding population. Figure FESPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin at 308 birds (the initial population for the western area - see Model Description). After a similar increase from 1965 to 1966, the predicted breeding populations quickly diverge under the two scenarios with C1995 increasing to a mean (calculated over 20 repetitions) of 500 breeding individuals by 1969 while under F2050 the breeding population slightly declines until 1971. The predicted breeding population under C1995 remains higher than under F2050 throughout the remainder of the model run, significantly so until 1980. Since the two scenarios produce the same trajectory over the model period the higher predicted populations under C1995 may be the result of the more favorable breeding conditions in the first three years under C1995. After the initial increase in breeding populations, both scenarios produce two peaks in predicted numbers (1978/1979 and 1991/1992) and one trough (1984/1985). Of these extreme breeding populations only the peak of 1978/1979 shows significant differences between the two scenarios with C1995 producing a mean breeding population of about 1800 individuals and F2050 producing 1100 individuals in 1979. The predicted breeding populations decline to 650 and 480 individuals under C1995 and F2050, respectively, in 1985. The populations then climb to 1950 and 1550 individuals under C1995 and F2050, respectively, in 1991/1992. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching just under 500 individuals in 1995 under both scenarios.

Figure FESPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV positively correspond with mean predicted breeding population (FESPMPOP.PDF). Suggesting that the stochastic nature of the model leads to higher variability with higher initial populations. Across all years, C1995 exhibits lower CVs than does F2050, never exceeding 0.15. Under F2050, after the fourth year the CV fluctuates between 0.15 and 0.3.

The fledgling productivity maps (FESPPROD.PDF) show that, averaging over all years, C1995 was more conducive to sparrow production than F2050 (FESPPROD.PDF: bottom). As discussed above, this initial difference in productivity (FESPPROD.PDF: top) resulted in higher predicted breeding populations under C1995 relative to F2050 for the first 15 model years. In 1994 (FESPPROD.PDF: middle), more fledgling were produced under F2050 relative to C1995 across the area studied. This was also the case in 1987 (not shown). For all other model years, C1995 produced more fledglings over more of the area than F2050. However, in ten years F2050 produced more fledglings in the northern one-third of occupied sparrow habitat.

D-C.8.10.1 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the model. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-")that the population will drop below a specified number over time. Under C1995, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the model period and a probability of 1.0 that it fall below 500 after two years (_ESPPTQX.PDF). Note that on this figure all of the lines are overlaid and only the last line (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050

(F_SPPTQX.PDF) there is a probability of 0.2 that the population will ever fall below 100 and a probability of 1.0 that the population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses F2050 shows an increasing probability of the population exceeding levels of up to 500 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching levels above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching levels above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under C1995 (_ESPPTQE.PDF), after 10 years the probability of reaching levels above 250 is 1.0 and above 500 is 0.9. After 25 years the probability of reaching levels above 1000 is 1.0 and above 2000 is 0.15. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the model. Under both scenarios (FESPPIER.PDF) the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 2000 breeding individuals is 0.5 under C1995 and 0.0 under F2050.

D-C.8.10.2 Conclusion

Under C1995 the sparrow breeding population reaches higher numbers early in the model years relative to F2050. This difference carries through until the final, high water years when the difference between the predicted breeding populations are insignificant. Overall, C1995 allows for higher fledgling productivity than F2050 and, partially as a consequence of this, C1995 breeding population estimates are less variable than those produced under F2050. The fledgling productivity maps show that, under either scenario, conditions are favorable enough for breeding sparrows to colonize nearly all available breeding habitat even though the model begins with the very constricted spatial distribution of breeding that we have witnessed in the recent high water years (compare FESPPROD.PDF top and middle).

D-C.8.11 Alternative A vs. F2050 (Revised)

SIMSPAR, unlike the breeding potential index model, provides a method of analyzing the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates population variability for the western sparrow breeding area. Results of the Alternative A scenario are shown in Fig. FASPTRAJ.PDF along with those from F2050.

Both F2050 and Alternative A lead to a persistent, although variable breeding population. Figure FASPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin with 308 birds (the initial population for the western area - see Model Description). Alternative A results consistently in significantly higher mean populations. The two predicted populations diverge after the first year of the simulation, and it may be this early difference that accounts for the subsequent higher populations under Alternative A. Both scenarios produce two peaks in predicted numbers (1979/1980 and 1991/1992) and one trough (1984/1985). Alternative A produces a mean breeding population of about 1600 individuals and F2050 produces 1100 individuals in 1978. Predicted breeding populations decline to 650 and 480 individuals under Alternative A and F2050, respectively, in 1985. The populations then climb to 2200 and 1550 individuals under Alternative A and F2050, respectively, in 1992. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 600 and 450 individuals for Alternative A and F2050, respectively, in 1995.

Figure FASPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV correlate positively with mean predicted breeding population (FASPMPOP.PDF), more so for F2050 than for Alternative A. After the first 4 years of the simulation, Alternative A exhibits lower CV's than does F2050. The lower CV's for Alternative A suggest that the ability of the population to reach higher numbers sooner, relative to F2050, allows for greater spatial distribution of breeders and, consequently, more stability in numbers between repetitions.

The fledgling productivity maps (FASPPROD.PDF) show that, averaging over all years, Alternative A is more conducive to sparrow production than F2050 (FASPPROD.PDF: bottom). In 1980 (FASPPROD.PDF: top), more fledglings were produced under F2050 relative to Alternative A across much the model area. This is the only year that F2050 produced more fledglings across the model area. In 14 other years, F2050 produced more fledglings in variously sized portions of the northern third of the model area. Even for these years, however, many more fledglings were produced under Alternative A over more of the model area than under F2050. In the extremely high water year of 1995 (FASPPROD.PDF: middle), Alternative A allows fledgling productivity over more of the study area, relative to F2050. Under both scenarios productivity is greatly reduced in 1995.

D-C.8.11.1 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the simulation. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative A, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the simulation period, a probability of 0.25 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after six years (_ASPPTQX.PDF). Note on this figure that all lines are overlaid and only the last line plotted (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF), there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that he population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses, F2050 shows an increasing probability of the breeding population exceeding levels of 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative A (_ASPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.9. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 1.0 that the population would reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FASPPIER.PDF), the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 1.0 under Alternative A and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 1.0 under Alternative A and 0 under F2050.

D-C.8.11.2 Conclusion

Relative differences between sparrow breeding population dynamics in the study area predicted under water regimes Alternative A and F2050 are significant, but complicated by the opposite effects that the scenarios have on sparrow breeding potential on either side of Shark River Slough. Generally, F2050 is more conducive to sparrow breeding east of the Slough and Alternative A is more conducive to breeding on the west side of the Slough. Since the BPI is not a quantitative measure, we are not able to determine the exact trade-off in predicted sparrow breeding given this spatially-based dichotomy. SIMSPAR is quantitative, and we show that the better breeding conditions west of the Slough under Alternative A relative to F2050 can lead to more sparrows. In the absence of a similar model for the area east of the Slough we are unable to determine which scenario is better for the global sparrow population.

An additional concern is that long-term habitat effects of conditions that are either too wet or too dry are difficult to assess with the BPI model. Specifically, long-term effects of dryness in the eastern area, which are difficult to measure, may counter-balance short-term effects of wet conditions, which are easily measured by counting days when water depths are above a threshold value for a given year. Hence, without a long-term vegetation change model, a scenario might be judged to be superior based on length of breeding season, when long-term changes in vegetative communities due to dryness under that water regime could lead to shrub invasion or changes in fire patterns. These, in turn, could have detrimental effects on sparrow breeding habitat.

D-C.8.12 Alternative B vs. F2050 (Revised)

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking into account the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates population variability for the western sparrow breeding area. Results of the Alternative B scenario are shown in Fig. FBSPTRAJ.PDF, along with those from F2050.

Both F2050 and Alternative B lead to a persistent, although variable, breeding population. Figure FBSPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin with 308 birds (the initial population for the western area - see Model Description). Alternative B results consistently in significantly higher mean populations. The two predicted populations diverge after the first year of the simulation and it may be this early difference that accounts for the subsequent higher populations under Alternative B. Both scenarios produce two peaks in predicted numbers (1979/1980 and 1991/1992) and one trough (1984/1985). Alternative B produces a mean breeding population of about 1550 individuals and F2050 produces 1100 individuals in 1978. Predicted breeding populations decline to 700 and 480 individuals under Alternative B and F2050, respectively, in 1985. The populations then climb to 2050 and 1550 individuals under Alternative B and F2050, respectively, in 1992. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 600 and 450 individuals for Alternative B and F2050, respectively, in 1995.

Figure FBSPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV correlate positively with mean predicted breeding population (FBSPMPOP.PDF), more so for F2050 than for Alternative B. After the first 6 years of the simulation, Alternative B exhibits lower CV's than does

F2050. The lower CV's for Alternative B suggest that the ability of the population to reach higher numbers sooner, relative to F2050, allows for greater spatial distribution of breeders and, consequently, more stability in numbers between repetitions.

The fledgling productivity maps (FBSPPROD.PDF) show that, averaging over all years, Alternative B is more conducive to sparrow production than F2050 (FBSPPROD.PDF: bottom). In 1978 (FBSPPROD.PDF: top), more fledglings were produced under F2050 relative to Alternative B across much the model area. This occurred for the year 1987 and 1980 as well (not shown). In six other years, F2050 produced more fledglings in only the northern part of the model area. For all other simulation years, more fledglings were produced under Alternative B over more of the model area than under F2050. In the extremely high water year of 1995 (FBSPPROD.PDF: middle), Alternative B allows fledgling productivity over more of the study area, relative to F2050. However, under both scenarios productivity is greatly reduced in 1995.

D-C.8.12.1 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the simulation. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative B, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the simulation period, a probability of 0.6 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after six years (_BSPPTQX.PDF). Note on this figure that all lines are overlaid and only the last line plotted (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF), there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that the population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses, F2050 shows an increasing probability of the breeding population exceeding levels of 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative B (_BSPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.5. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 0.75 that the population will reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FBSPPIER.PDF), the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 1.0 under Alternative B and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 0.75 under Alternative B and 0 under F2050.

D-C.8.12.2 Conclusion

Relative differences between sparrow breeding population dynamics in the study area predicted under water regimes Alternative B and F2050 are significant, but complicated by the opposite effects that the scenarios have on sparrow breeding potential on either side of Shark River Slough. Generally, F2050 is more conducive to sparrow breeding east of the slough and Alternative B is more conducive to breeding on the west side of the slough. Since the BPI is not a quantitative measure we are not able to determine the exact trade-off in predicted sparrow breeding given this spatially based dichotomy. The SIMSPAR model is quantitative, and shows that the better breeding conditions west of the slough under Alternative B relative to F2050 can lead to more sparrows. In the absence of a similar model for the area east of the slough we are unable to determine which scenario is better for the global sparrow population.

An additional concern is that long-term habitat effects of conditions that are either too wet or too dry are difficult to assess with the BPI model. Specifically, long-term effects of dryness in the eastern area, which are difficult to measure, may counter-balance short-term effects of wet conditions, which are easily measured by counting days when water depths are above a threshhold value for a given year. Hence, without a long-term vegetation change model, a scenario might be judged to be superior based on length of breeding season, when long-term changes in vegetative communities due to dryness under that water regime could lead to shrub invasion or changes in fire patterns. These, in turn, could have detrimental effects on sparrow breeding habitat.

D-C.8.13 Alternative C vs. F2050 (Revised)

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates population variability for the western sparrow breeding area. Results of the Alternative C scenario are shown in Fig. FCSPTRAJ.PDF along with those from F2050.

Both F2050 and Alternative C lead to a persistent, although variable breeding population. Figure FCSPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin with 308 birds (the initial population for the western area - see Model Description). Predicted breeding populations under the two scenarios are very similar through time. Alternative C results in significantly higher mean populations only from 1967 through 1977. Both scenarios produce two peaks in predicted numbers (1978/1979 and 1991/1992) and one trough (1984/1985). Alternative C produces a mean breeding population of about 1400 individuals and F2050 produces 1100 individuals in 1978. Predicted breeding populations decline to 500 and 480 individuals under Alternative C and F2050, respectively, in 1985. The populations then climb to 1750 and 1550 individuals under Alternative C and F2050, respectively, in 1992. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 500 individuals in 1995 under both scenarios.

Figure FCSPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV correlate positively with mean predicted breeding population (FCSPMPOP.PDF). Through the 1970's and through the 1990's, Alternative C exhibits lower CV's than does F2050. Although the CV's of both scenarios are similar, the lower values in the crucial wet years of 1992 - 1995 for Alternative C suggest that the breeding population has more of a chance of persisting through extreme conditions under this scenario relative to F2050.

The fledgling productivity maps (FCSPPROD.PDF) show that, averaging over all years, Alternative C is more conducive to sparrow production than F2050 (FCSPPROD.PDF: bottom). In 1980 (FCSPPROD.PDF: top), more fledglings were produced under F2050 relative to Alternative C across the area studied. This was also the case in 1978, 1980, 1987, and 1992 (not shown). For all other model years, more fledglings were produced under Alternative C over more of the model area than under F2050. However, for eight of these years (not shown) more fledglings were produced under F2050 in parts of the model area. In the extremely high water year of 1995 (FCSPPROD.PDF: middle), Alternative C allows fledgling productivity over more of the study area, relative to F2050. However, under both scenarios productivity is greatly reduced in 1995.

D-C.8.13.1 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the model. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative C, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the model period, a probability of 0.9 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after one year (_CSPPTQX.PDF). Note on this figure that all lines are overlaid and only the last line plotted (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF), there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that the population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses, F2050 shows an increasing probability of the breeding population exceeding levels of 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative C (_CSPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.45. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 0.05 that the population would reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FCSPPIER.PDF), the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 0.95 under Alternative C and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 0.10 under Alternative C and 0 under F2050.

D-C.8.13.2 Conclusion

Relative differences between sparrow breeding population dynamics in the study area predicted under water regimes Alternative C and F2050 are minor. Alternative C appears to be more conducive to breeding population recovery after a decline relative to F2050. This is apparent in the fledgling productivity maps and the PVA results.

D-C.8.14 Alternative D vs. F2050 (Revised)

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates population variability for the western sparrow breeding area. Results of the Alternative D scenario are shown in Fig. FDSPTRAJ.PDF along with those from F2050.

Both F2050 and Alternative D lead to a persistent, although variable breeding population. Figure FDSPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin with 308 birds (the initial population for the western area - see Model Description). Predicted breeding populations under the two scenarios are very similar through time. Alternative D results in significantly higher mean populations only from 1973 through 1977. Both scenarios produce two peaks in predicted numbers (1978/1979 and 1991/1992) and one trough (1984/1985). Alternative D produces a mean breeding population of about 1400 individuals and F2050 produces 1100 individuals in 1978. Predicted breeding populations decline to 600 and 480 individuals under Alternative D and F2050, respectively, in 1985. The populations then climb to 1750 and 1550 individuals under Alternative D and F2050, respectively, in 1991. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 500 individuals in 1995 under both scenarios.

Figure FDSPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV positively correspond with mean predicted breeding population (FDSPMPOP.PDF). From 1975 onwards, Alternative D exhibits lower CV's than does F2050, never exceeding 0.20. Under F2050, after the fourth year the CV fluctuates between 0.15 and 0.3.

The fledgling productivity maps (FDSPPROD.PDF) show that, averaging over all years, Alternative D is more conducive to sparrow production than F2050 (FDSPPROD.PDF: bottom). In 1980 (FDSPPROD.PDF: top), more fledglings were produced under F2050 relative to Alternative D across the area studied. This was also the case in 1978 and 1987 (not shown). For all other model years, more fledglings were produced over more of the model area under Alternative D than under F2050. However, for nine of these years (not shown) more fledglings were produced in portions of the model area under F2050. In the extremely high water year of 1995, higher fledgling productivity is seen under Alternative D (FDSPPROD.PDF: middle).

D-C.8.14.1 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the model. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative D, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the model period, a probability of 0.8 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after one year (_DSPPTQX.PDF). Note on this figure that all lines are overlaid and only the last line plotted (e.g., 500) is visible, this implies that all values above 500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF), there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that the population will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses, F2050 shows an increasing probability of the breeding population exceeding levels of 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative D (_DSPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.3. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 0.15 that the population would reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FDSPPIER.PDF), the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 0.95 under Alternative D and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 0.10 under Alternative D and 0 under F2050.

D-C.8.14.2 8.14.2 Conclusion

Relative differences between sparrow breeding population dynamics in the study area predicted under water regimes Alternative D and F2050 are minor. Alternative D appears to be more conducive to breeding population recovery after a decline relative to F2050. This is apparent in the fledgling productivity maps and the PVA results.

D-C.8.15 Alternative D13 vs. F2050 (Revised)

SIMSPAR, unlike the breeding potential index model, provides a method to analyze the complete history of population trends, taking account of the detailed effects of localized water dynamics on individual bird growth, survival, and reproduction. SIMSPAR produces population trajectories and calculates the population variability for the western sparrow breeding area. Results of the Alternative D13R scenario are shown on FGSPTRAJ.PDF, along with those from F2050.

Both F2050 and Alternative D13R lead to a persistent, although variable breeding population. Figure FGSPMPOP.PDF shows the mean predicted number of breeding individuals under each scenario. Both scenarios begin at 308 birds (the initial population for the western area - see Model Description). The predicted breeding populations under the two scenarios are very similar through time. Alternative D13R results in significantly higher mean populations only from 1967 through 1970 and from 1972 through 1977. Both scenarios produce two peaks in predicted numbers (1978/1979 and 1991/1992) and one trough (1984/1985). Alternative D13R produces a mean breeding population of about 1400 individuals and F2050 producing 1100 individuals in 1978. The predicted breeding populations decline to 600 and 480 individuals under Alternative D13R and F2050, respectively, in 1985. The populations then climb to 1750 and 1550 individuals under Alternative D13R and F2050, respectively, in 1991. Finally, with the onset of a series of high water years, both predicted breeding populations begin to decline, reaching about 500 individuals in 1995 under both scenarios.

Figure FGSPCVAR.PDF shows the coefficient of variation (CV) for each year calculated over replicates. Values of CV positively correspond with mean predicted breeding population (FGSPMPOP.PDF). From 1975 onwards, Alternative D13R exhibits lower CV's than does F2050, never exceeding 0.20. Under F2050, after the fourth year the CV fluctuates between 0.15 and 0.3.

The fledgling productivity maps (FGSPPROD.PDF) show that, averaging over all years, Alternative D13R was more conducive to sparrow production than F2050 (FGSPPROD.PDF: bottom). In 1980 (FGSPPROD.PDF: top), more fledgling were produced under F2050 relative to Alternative D13R across the area studied. This was also the case in 1978 and 1987 (not shown). For all other simulation years, Alternative D13R produced more fledglings over more of the area than F2050 did. However, for nine of these years (not shown) F2050 produced more fledglings in parts of the model area. In the extremely high water year of 1995, Alternative D13R allows higher fledgling productivity (FGSPPROD.PDF: middle).

D-C.8.15.1 Population Viability Analysis

The Population Viability Analysis (PVA) consists of 3 parts: time to quasi-extinction; time to quasi- explosion; and interval explosion risk. For each of these analyses we started calculations at 5 years after the start time for the simulation. Time to quasi-extinction is the cumulative probability (based on replicates, thus the term "quasi-") that the population will drop below a specified number over time. Under Alternative D13R, there is a probability of 0 that the sparrow breeding population will drop below 100 individuals over the simulation period, a probability of 0.9 that it will fall below 250, and a probability of 1.0 that it will fall below 500 after one year (_GSPPTQX.PDF). Note that on this figure all of the lines are overlaid and only the last line (e.g., 500) is visible, this implies that all values above

500 in the figure legend have the same probability. For F2050 (F_SPPTQX.PDF) there is a probability of 0.2 that the breeding population will ever fall below 100 and a probability of 1.0 that it will drop below 250.

Time to quasi-explosion is the converse of time to quasi-extinction. It estimates the probability that the population will exceed a specified number over time. As time progresses F2050 shows an increasing probability of the breeding population exceeding levels of up to 1000 individuals (F_SPPTQE.PDF). After 10 years the probability of reaching a level above 100 is 1.0 and above 250 is 0.4. After 25 years the probability of reaching a level above 500 is 1.0 and above 1000 is 0.7. There is a zero probability that the population will ever exceed 2000 individuals. Under Alternative D13R (_GSPPTQE.PDF), after 10 years the probability of reaching a level above 250 breeding birds is 1.0 and above 500 is 0.2. After 25 years the probability of reaching a level above 1000 is 1.0 and over 30 years there is a probability of 0.2 that the population would reach 2000. There is a zero probability that the population will ever exceed 3000 individuals.

Interval explosion risk is the probability that the population will reach a certain number over the period of the simulation. Under both scenarios (FGSPPIER.PDF) the probability that the breeding population would grow to more than 1000 individuals over a 31-year period is 1.0. The probability of reaching 1500 breeding individuals is 1.0 under Alternative D13R and 0.65 under F2050. The probability of reaching 2000 breeding individuals is 0.2 under Alternative D13R and 0 under F2050.

D-C.8.15.2 Conclusion

Alternative D13R produces lower BPI values relative to F2050 in the eastern sparrow breeding area and in the southern portion of the western breeding area under most hydrologic conditions. The results of SIMSPAR suggest that the sparrow population can reach higher levels more often under Alternative D13R, relative to F2050. Alternative D13R also produces a more stable sparrow population and it appears to be more conducive to breeding population recovery after a decline relative to F2050. This is apparent in the fledgling productivity maps and the PVA results.

WATER QUALITY ANALYSIS

D-D.1 BACKGROUND

The effect of Restudy alternatives on water quality conditions in the study area was one of the evaluations conducted for the Alternative Evaluation Team (AET). To perform these evaluations, an ad hoc Water Quality Team (WQT) was created to evaluate the base conditions and the alternative plans. The WQT was co-chaired by USEPA and FDEP, and consisted of staff from several Federal, state, tribal, regional, and local agencies. The WQT consisted of staff from the following agencies: USEPA, FDEP, SFWMD, USACE, FDACS, ENP, LNWR, USFWS, BCNP, NOAA/NMFS, Seminole Tribe, Palm Beach County, Broward County, Miami-Dade County.

The WQT evaluated each of the alternative plans created by the Alternative Development Team (ADT), and provided comments and recommendations for optimizing the overall performance of the alternative plans from a water quality perspective and to achieve water quality objectives.

The WQT utilized output from two water quality models to evaluate the relative performance of the alternative plans compared to current (1995) and future (2050) base conditions: the Lake Okeechobee Water Quality Model (LOWQM), which simulates conditions for certain water quality parameters within Lake Okeechobee; and, the Everglades Water Quality Model (EWQM), which simulates water column phosphorus concentrations and loads within the Everglades Protection Area. Both of the models use hydrologic output from the SFWMM to simulate water quality conditions resulting from the implementation of a Restudy alternative plan.

A third evaluation was conducted by William W. Walker, Jr. examining the effect of Restudy alternatives on the performance of the Everglades Construction Project (ECP). Walker's evaluation specifically examined the function of Component G5 (EAA Reservoir) and the projected performance of each STAs of the ECP compared to several performance targets for the ECP.

The WQT also utilized SFWMM hydrologic output for individual components in each alternative to assess potential pollution load reduction performance of the reservoirs/water storage areas and to identify potential water quality "hot spots" indicated by significant changes in water quantity (31-year average annual volumes) and discharge locations. The WQT further considered the components in the context of current regulatory programs (particularly the Everglades Program authorized under the EFA), designated use classifications pursuant to the State of

Florida's water quality standards contained in FAC Rule 62-302, and other special classifications (OFW, etc).

D-D.2 EVALUATION METHODOLOGY

For purposes of evaluating the overall performance of the base conditions and the alternative plans, the WQT divided the study area into logical sub-regions, based on the modeling and evaluation tools available and geographical distinctions. Due to model boundaries and performance measures/indicators, the WQT's sub-regions differed somewhat from the geographical scope and boundaries of the "study regions" created by the Restudy Team. For example, Florida Bay is within the ENP study region, but was not included within the ENP sub-region as part of the WQT's evaluation (no model or other evaluation output available with which to measure water quality performance). The following sub-regions were developed by the WQT for purposes of evaluating water quality for the base conditions and the alternative plans:

Lake Okeechobee;
Everglades Agricultural Area/ECP;
WCAs 2 and 3;
St. Lucie River watershed
Caloosahatchee River watershed
Loxahatchee National Wildlife Refuge
Everglades National Park
Lower East Coast

Because there are, at present, no water quality models or other quantitative evaluation tools which can be linked to hydrologic changes in the study area resulting from implementation of Restudy alternative plans, the WQT did not quantitatively evaluate water quality performance in the Kissimmee River region, Holeyland and Rotenberger WMAs, Big Cypress National Preserve, Florida Bay, and the Florida Keys. It is expected that future versions of the Everglades Landscape Model (ELM) and other water quality models will be developed which will have the capability of simulating water quality conditions in some or all of the geographic regions of the Restudy area.

Upon completion of each of the SFWMM alternative runs and subsequent posting of the hydrologic performance measures, the WQT evaluated the Starting Point, Alternatives 1-5, Alternatives A-D, and Alternative D13R. Using SFWMM output, the two water quality models (LOWQM, EWQM) were run. Concurrently, Walker's evaluation was completed for each of the alternatives as SFWMM output pertinent to the EAA/ECP became available.

The WQT met collectively to review and interpret results and prepare recommendations to the AET. In addition to evaluating the overall performance of the alternative plans, the WQT assessed the potential impact and/or benefits of individual plan components. The Team met approximately 12 times during the plan formulation and evaluation phase of the Restudy between August, 1997 and July, 1998. This iterative approach enabled the WQT to develop and improve water quality performance measures and indicators, gauge improvements in the overall performance of the alternatives from a water quality perspective, discuss water quality issues inherent in hydrologic changes from alternative run to alternative run, and to come to consensus on recommendations to be forwarded to the AET.

At the conclusion of the modeling of the alternatives, the Team ranked the alternatives based on cumulative performance within the sub-regions using selected key performance measures/indicators. Matrices for each of the sub-regions were created comparing the alternatives and base conditions (see Tables D-D-2 to D-D-7). A combined ranking matrix was prepared from which to assess the overall performance of the alternatives and conclusions and recommendations were reported to the AET. Subsequent to the creation of Alternative D13R, the Team met again to evaluate that alternative from a water quality perspective. A second ranking matrix was prepared which combined water quality performance for the two base conditions and Alternatives A through D13R (see D-D-1). The Team's consensus conclusions and recommendations were then forwarded to the Restudy Team.

D-D.3 PERFORMANCE MEASURES AND INDICATORS

The WQT evaluated the performance of the base conditions and alternative plans in the context of performance measures (which are water quality targets; e.g., 10 ppb water column phosphorus concentration) and performance indicators (which lack specific targets, but indicate relative performance; e.g., percentage of time stage maintained).

The following LOWQM performance measures/indicators were evaluated:

Average lake volume;
Average in-lake phosphorus concentration;
Average in-lake chlorophyll a concentration;
Average blue-green algae concentration;
Box-plot comparisons of phosphorus, chlorophyll a, and blue-green algae;
Differences from future (2050) base concentrations for phosphorus, chlorophyll a, and blue-green algae;
Phosphorus inflow (into lake) loads;
Phosphorus outflow (out of lake) loads;

Wet year (1995) phosphorus inflow and outflow loads;
Dry year (1984) phosphorus inflow and outflow loads; and
Cumulative phosphorus fluxes to lake sediments.

The following EWQM performance measures/indicators were evaluated:

Mean grid cell water column phosphorus concentrations within the Everglades Protection Area (EPA) by basin;
14-station (per Settlement Agreement) geometric mean phosphorus concentration within LNWR;
14-station geometric mean phosphorus concentration, LWNR (wet year and dry year);
Mean annual structural phosphorus loads into the EPA by basin;
Mean annual basin phosphorus concentration;
Mean annual combined structural phosphorus load from S-12s/S-333; and
Mean annual combined phosphorus concentration at S-12s/S-333 (per Settlement Agreement).

The following SFWMM performance measures/indicators were evaluated:
Stage Duration Curves and Stage Hydrographs for all of the reservoirs included in the alternative plans (North Reservoir, Taylor Creek/Nubbins Slough Reservoir, St. Lucie Reservoir, Caloosahatchee Reservoir, EAA Reservoir, Site 1 Reservoir, C-11 Reservoir, C-9 Reservoir, Central Lake Belt Reservoir, North Lake Belt Reservoir, Bird Drive Reservoir); Report, Lake Okeechobee Water Budget; Water budget data from FTP site.

In addition to the above-listed performance measures/indicators, William W. Walker created 24 key performance indicators illustrating the effect of the future base condition and Restudy alternative plans on the performance of the ECP (see Tables 7a – 7f).

D-D.4 RESULTS

A summary of the Water Quality Team’s conclusions and recommendations is included below in ***Table D-D-1***.

TABLE 1
Restudy Water Quality Team's
Combined *Ranking* Matrix

The Base Conditions and alternative plans were ranked on a scale of 1-7, with higher scores indicating a more preferred condition from a water quality perspective.

Subregion	**95B**	**50B**	**A**	**B**	**C**	**D**	**D13R**
1. Lake Okeechobee (see footnote 1)	2.5	2.5	2.5	6.5	4.5	6.5	4.5
2. EAA/ECP	1	3.5	7	6	3.5	2	5
3. WCAs 2 & 3 (see footnote 2)	1	6	7	2	3	4.5	4.5
4. St. Lucie Watershed	1	2	3.5	3.5	5	6	7
5. Caloosahatchee Watershed	1.5	1.5	3	4	5	6.5	6.5
6. LNWR	1	2	5	5	5	5	5
7. ENP	1.5	5	3.5	6.5	1.5	3.5	6.5
8. LEC (see footnote 3)	4.5	4.5	1	2	3	6.5	6.5
Cumulative Score	***14***	***27***	***32.5***	***35.5***	***30.5***	***40.5***	***45.5***

Footnotes

1. Ranking of alternatives for Lake Okeechobee is based on evaluation of selected performance indicators. Comparing alternatives, differences greater than one percent in relative performance calculated by the model were assigned different ranks. Although the differences between simulated conditions for the alternatives are within the uncertainty of the model, the Water Quality Team felt it was important to rank the plans for Lake Okeechobee from a water quality perspective.

2. Water Conservation Areas 2 & 3 rankings were weighted to account for relative size (acreage).

3. Ranking of the alternatives based on an evaluation of potential water quality impacts/benefits in the LEC is primarily based upon salinity targets in Lake Worth and Biscayne Bay. The presumed water quality benefits resulting from an evaluation of the hydraulic performance of selected reservoirs were also evaluated. For those performance indicators, a score of zero was

assigned to alternatives for which no hydraulic performance for the reservoirs was observed.

Recommendations to Restudy Team

1. From a water quality perspective, Alternative D13R is preferred over Alternatives B, A, & C. The 95 Base and the 50 Base were not acceptable.

2. The Water Quality Team determined that the Base Conditions and alternative plans should not be ranked based upon the U. S. Environmental Protection Agency's preliminary mercury model results (model needs further development). Atmospheric deposition is the dominant contributor of mercury in the Everglades Protection Area. Restudy alternative plans are not expected to significantly affect mercury in the Everglades Protection Area.

3. Due to a lack of model results (particularly Everglades Landscape Model results), Restudy alternative plans could not be ranked based upon an empirical evaluation of water quality impacts or benefits in Big Cypress National Preserve and the Holeyland and Rotenberger Wildlife Management Areas.

D-D.5 ISSUES OF CONCERN

Restudy components must meet State and Tribal water quality standards, as appropriate. In particular, increased flows to the Everglades Protection Area EPA (over that which is in the Future Base condition, i.e. Everglades Forever Act fully implemented) must meet the yet-to-be-established numeric phosphorus criteria for the EPA (default concentration = 10 parts per billion). The technology (and hydrologic demands, if any) required to achieve this standard has not yet been determined. Furthermore, it can be reasonably assumed that the technology (and concurrent land and hydrologic demands) will vary for Restudy components, depending upon location (e.g., runoff originating from agricultural lands with peat soils, compared to runoff originating from rock-plowed agricultural lands or lands with marl soils or urban runoff). Component design should continue to take into account current and future land uses in the vicinity of the components and the estimated land acquisition, construction, and operations costs to assure that water quality treatment facilities necessary to meet water quality standards are included in the final design.

Additionally, treatment costs may not be limited to just those necessary to achieve surface water standards. Restudy components capable of polluting groundwater (ASR, discharges in the vicinity of underground drinking water sources) must include treatment necessary to achieve groundwater quality standards prior to introduction of discharges into the groundwater.

The Team does not expect to observe a significant recovery of Lake Okeechobee during the simulation period for the models (23 years for the LOWQM). Therefore, the long-term benefits of treatment facilities and wetlands restoration in the Lake Okeechobee watershed are not readily observable in the water quality performance indicators which are available to evaluate the affect of the Restudy on the lake. Although modeling results may lead one to empirically conclude that there are no observable water quality benefits to Lake Okeechobee achieved by including water quality treatment features in the Initial Draft Plan (IDP) components when compared to Future Base Conditions, the WQT intuitively concludes that such projects and facilities will create long-term water quality benefits in Lake Okeechobee beyond the planning horizon for the Restudy.

Although the Team concurs with the method for determining mean phosphorus concentration values in the Taylor Creek/Nubbins Slough basin (528 ppb), additional information is needed about the design and operation of the STA (Component W2) proposed for that basin. While it is understood that more detailed information about the design and operation of this component would occur in future detailed design work if this component is included in the final comprehensive plan, it is noted that the STA is assumed to achieve an 80% reduction in basin loads and concentrations prior to discharge to Lake Okeechobee (this efficiency is at the upper end of the range of phosphorus reduction efficiency for STAs).

Furthermore, the WQT has not determined that 107 ppb is the correct target concentration for discharges to Lake Okeechobee (this concentration will not necessarily contribute to a reduction of ambient lake water column phosphorus concentrations below the current mean concentration of approximately 100 ppb; the Lake Okeechobee SWIM Plan update indicates that 40 ppb is the target in-lake concentration). Additional treatment works may be necessary to achieve target concentrations.

Alternative D13R increases the volume of water delivered from the ECP to the downstream WCAs by 19 percent compared to that delivered by the conceptual design utilizing the same baseline period (1979-1988). Increasing the volume of water delivered to the WCAs to achieve environmental and water supply objectives of the Restudy contributes towards achieving the 28 percent increase to the WCAs requirement contained in the EFA (F.S. 373.4592(4)(b)2). The 19 percent increase is to be achieved concurrent with other components designed to achieve optimal hydrological conditions in the Everglades. No alternative plan delivered more than 23 percent (Alternative B) greater flows via the ECP to the WCAs (see Table D-D-7b).

Components K6, X6, and Y6 involve increasing the amount of water contained within the West Palm Beach Water Catchment Area. This involves collecting runoff from the L-8, C-51, and C-17 watersheds (Class III waters), and directing it via the M-Canal and C-18 Canal to the Water Catchment Area. The C-18 Canal, M-Canal, the Water Catchment Area and Lake Mangonia are all Class I waters (Potable Water Supply). To receive water quality certification under the Clean Water Act, Restudy components which create new surface waters discharges into Class I waters would have to discharge water of sufficient quality to assure that the Class I use classification is maintained. While it is understood that the design of the components include STAs to address water quality treatment requirements, additional treatment works (over and above vegetated STAs) may be necessary to assure compliance with Class I water quality standards. To further evaluate future treatment requirements, if any, ambient pollutant loads and concentrations within the watersheds would have to be quantified and compared against minimum, general, and Class I surface waters criteria contained within Florida Administrative Code Rule 62-302.

Components D5 and GG4 involve storing Lake Okeechobee and Caloosahatchee River watershed runoff in 22 10 MGD and 200 5 MGD aquifer storage and recovery (ASR) wells, creating a total of 1,220 MGD of surface water to be injected and stored in the Floridan aquifer. These components create significant hydrologic benefits, especially in the lake. However, there are some assumptions about Lake Okeechobee and Caloosahatchee ASR as presently modeled. The technical feasibility of injecting and a 70% recovery of 1,220 MGD has not yet been proven, nor has ASR on this scale been implemented anywhere that the WQT is aware of. Second, the water quality and ecological impacts of recovering water stored in the aquifer and discharging it directly to Lake Okeechobee (Class I waters) and Caloosahatchee basin waters (Class III waters) have not been reasonably evaluated. The WQT has been made aware that the potential impacts include possible increased production of methylmercury, changes in pH and temperature, and the introduction of water containing low-to-no dissolved oxygen. Water which is recovered from ASR wells may require additional treatment (e.g., wetlands) prior to discharging to Class I (Lake Okeechobee) and Class III (Caloosahatchee basin) surface waters to maintain the use classifications and ecological integrity of those waters and downstream receiving waters. Further detailed evaluation of ASR water quality and its impact on surface waters is necessary. An ad hoc ASR Team is being created for such a purpose. However, since it may not be possible to complete such an evaluation given the schedule for drafting a feasibility report and a PEIS for the Restudy, the Restudy Team should consider including additional treatment facilities and costs in the comprehensive plan to achieve and maintain water quality and ecological targets in Lake Okeechobee and Caloosahatchee basin waters potentially affected by ASR water.

Component DDD5 involves discharging Caloosahatchee basin runoff through an STA into Lake Okeechobee. New discharges to Lake Okeechobee must meet Class I drinking water standards.

D-D.6 ADDITIONAL RECOMMENDATIONS

The surface water storage reservoirs (approximately 184,000 acres in the IDP) should be operated to optimally capture phosphorus contained in inflows and remove phosphorus from outflows. To the extent that phosphorus is a surrogate for other pollutants, optimal operation of these facilities for phosphorus removal will contribute to additional significant pollution load reductions. The Team's present recommendation for optimal operation is to maintain at least 2.5-ft. water depth in the reservoirs, with a minimum hydraulic retention (residence) time of 21 days prior to discharge. When the surface water reservoirs dry down (when depths fall below 2.5 ft.), upon re-wetting, the same optimal hydrologic operational scenario should be achieved prior to discharge.

The implications of the increased volume delivered to the ECP via the IDP on the "Phase 2" treatment requirement should be further evaluated. The STA Design Group, Everglades Technical Advisory Committee, or technical staff in support of the Technical Oversight Committee established by the Settlement Agreement could facilitate such an evaluation. Walker's evaluation indicates that future "without project" and IDP hydraulic flows and phosphorus loads could create potential performance problems in the STAs absent Phase 2 treatment facilities. Supplemental treatment technologies presently being investigated by SFWMD to achieve low phosphorus concentrations in anticipation of the yet-to-be-established numeric phosphorus criterion for the EPA utilize hydrologic records from 1979-1988 baseline period used in the Conceptual Design for the ECP (Burns & McDonnell, 1994). The WQT recommends that the 31-year 1965-1995 hydrologic period of record be used for such investigations.

The IDP creates an increase over the 2050 Base Condition in the volume of Lake Okeechobee water delivered to LEC Service Area 2 to meet water supply demands. A preliminary analysis of the partitioning of water deliveries to and through the Water Conservation Areas indicates that under certain conditions, water delivered from Lake Okeechobee to the Lower East Coast has the potential to increase phosphorus loads in the Water Conservation Areas. Given the potential for increased phosphorus loads associated with water supply deliveries from Lake Okeechobee to the LEC to create ecological impacts in the Everglades marsh, the WQT recommends that alternative sources of water to meet LEC SA2 demands be investigated (e.g. wastewater reuse in Broward County).

Given that water depths in southern LNWR exceed that predicted by the NSM, the WQT recommends that the hydrologic effect of re-directing Acme Basins discharges be further evaluated by the Restudy Team (e.g. re-directed to the LEC, or re-directed to WCA 2 after treatment). Water budget data indicate that approximately 39 k ac. ft. (average annual volume) is delivered to LNWR from the

Acme Basins (Wellington area). Acme Basins water consists of agricultural and urban runoff, which is presently untreated. The Non-ECP requirements of the EFA, when fully implemented, require that water quality strategies (e.g. BMPs, treatment facilities, land acquisition) be implemented to assure that all water quality standards are met by 12/31/06, including the yet-to-be-established numeric criterion for phosphorus. However, if excess Acme Basins water could be re-directed for other uses (water supply, wellfield enhancement, etc), hydrologic and water quality benefits could be realized in LNWR, along with a concomitant reduction in future expenditures necessary to meet the requirements of the EFA.

Water budget data for Lake Okeechobee show that approximately 79 k ac. ft. of water from the Northern L-8 Basin is discharged to Lake Okeechobee. This is the same condition as the 2050 Base (discharges without treatment). Water quality data for the structures through which these flows pass indicate that Northern L-8 water contains relatively high concentrations of total phosphorus (over 200 ppb). Lake Okeechobee water discharges to the Everglades to meet hydrologic targets and to the LEC through the Everglades create performance problems for ECP (in the case of increasing lake flows to the ECP over the design flows) and increase phosphorus loading in the Everglades. The WQT has identified several options for treating or re-directing Northern L-8 Basin water: 1) treatment of water (STAs, etc.) prior to backpumping to Lake Okeechobee to reduce in-lake phosphorus loads and subsequent downstream loads to the ECP and the EPA; 2) creation of additional storage; and 3) routing a portion of Northern L-8 Basin flows south to LNWR via a flow-way or through STA 1E to meet hydrologic targets in northern LNWR.

Attachment E
Final AET Report on the D13R4 Scenario

D-E.1 OVERVIEW

The Alternative Evaluation Team for the C&SF Restudy conducted a preliminary evaluation of the D13R4 scenario during a meeting of the full AET on 20 January 1999. The objective of this modeling exercise was to determine the feasibility of improving D13R, by capturing additional surplus water from the amount discharged to tide each year, and of conveying that "new" water (plus redistributing excessive water in the Water Conservation Areas) to better meet performance targets in the natural system. Scenarios designed to convey urban runoff water into the natural system have not previously been considered during the lengthy AET/ADT plan formulation process. The D13R4 scenario reported on here was clearly the most successful of four scenarios (R1–R4) that were developed during an intensive, multi-agency planning and modeling process, which began in November 1998.

The AET found that the overall performance of Scenario D13R4, as modeled on 13-14 January, included both gains and losses when measured against the 1995 base, 2050 base, and D13R conditions. D13R4 captured an average of 253,000 acre feet/year of new water for the natural system from Palm Beach and Broward counties. This new water, combined with excessive water from the WCAs, provided an average of 271,000 acre feet of new water each year to Everglades National Park and an average of 77,000 acre feet of new water to Biscayne Bay each year. The increased annual mean flows to the park and Biscayne Bay are expected to produce substantial improvements towards meeting the hydrological performance targets for these two areas. Although D13R4 also provided modest improvements in northeast WCA 3A and northeast 2B, by reducing the number of undesirable high water events in these two subregions, this scenario increased the number of undesirable high water events in WCAs 2A and 3B to a level greater than that predicted for the two base conditions. D13R4 also created undesirable increases in the depth and duration of flooding in the Pennsuco wetlands. By delivering urban water to the natural system, this scenario raises a number of new water quality questions.

The AET recognizes that much new information regarding the potential performance of D13R was gained during the modeling of the four scenarios R1-R4 of D13R. The hydrological responses during the modeling of these four scenarios convincingly demonstrated the operational flexibility of D13R, and offers encouraging documentation that additional improvements can be achieved during the detailed planning phases of the restoration program.

Table 1
Details of Flows to Tide
Thousand Acre Feet/year

C-16 @ S-41	**90**	**31**	**13**	**+18**
C-15 @ S-40	**94**	**33**	**13**	**+20**
Hillsboro @ G-56	**125**	**28**	**29**	**-1**
PBC subtotal	684	265	129	+136
C-14 @ S-37A	**106**	**97**	**49**	**+48**
C-13 @ S-36	**53**	**25**	**15**	**+10**
NNR @ G-54	**69**	**99**	**40**	**+59**
Broward subtotal	228	221	104	+117

The AET recommended that the specific features of D13R4 that allowed for the capture and conveyance of substantial amounts of new water for the natural system be incorporated into the Recommended Plan, D13R, contingent upon:

- Finding ways to reduce the number of damaging high water events in WCA 2A and 3B to a level at or below the level predicted for D13R.
- Adequately treating the stormwater runoff from the C-51 east/C-13/14 basins directed into the Everglades Protection Area to meet all state and federal water quality standards to enable ecological restoration to be achieved.
- Moderating excessive high water events in the Pennsuco wetlands.

It was agreed that these concerns can best be resolved during the finer scale modeling and planning which will occur as a part of detail design work. The addition of these features should allow greater operational flexibility during future efforts to improve the overall performance of D13R. An issue paper may be required from the Restudy's water quality team, to more fully explore the questions being raised by the use of urban water to meet natural system targets in Everglades National Park.

D-E.2 "BULLET" SUMMARY EVALUATIONS OF D13R4

D-E.2.1 Water Quality

For the first time, 253,000 acre feet/year of urban runoff was captured, treated, and sent into the natural system to augment flows to Everglades National Park and Biscayne Bay, raising the following questions:

- D13R4 assumes that the technology exists for treating urban stormwater for a whole suite of water quality parameters beyond nutrients.
- There may not be sufficient land available to adequately treat the volume of wet season runoff this scenario requires.
- Due to complex pollutant loads associated with urban runoff, future permitting of new discharges of treated urban runoff to Outstanding Florida Waters (ENP & Biscayne Bay) is expected to be difficult for the responsible regulatory agencies.
- The additional treatment and routing facilities add a new layer of complexity to the sequencing of the implementation plan
- Benefits of the new water will not be seen until all necessary water treatment components are up and running.

D-E.2.2 Total System

- Connectivity was similar to D13R except for an increase in extreme depth differences between WCA-2 and WCA-3.
- Sheetflow in WCA-2B showed an NSM-like pattern for the first time. Flows also improved across Tamiami Trail east of L-67 and the eastern part of Everglades National Park.
- Fragmentation was the same as D13R. No additional canals and levees were removed within the natural system.

D-E.2.3 Northern Estuaries

- Caloosahatchee: No change.
- St Lucie Estuary: One additional discharge event over the 31-year period of record.
- Lake Worth: Far fewer adverse discharges of fresh water.

D-E.2.4 Lake Okeechobee

- No change.

D-E.2.5 Lower East Coast

- Water supply performance is the same as D13R except there are two additional months in Broward County of low water conditions along the coast in the 31-year period of record.

D-E.2.6 Northern and Central Everglades

- Eastern and northeastern WCA-3A and WCA-2B are better, but still far from the NSM envelope. New problems arose in WCA-2A and WCA-3B. The modest benefits were seen in some of the more degraded areas but serious problems developed in more pristine parts of the system.

- Southern WCA-2A: Much worse than all plans and base conditions in extreme high water and extreme low water conditions. Increasing the flows through WCA-2A during the wet season only raised depths without helping increase hydroperiods into the dry season.

- WCA-2B: Extreme lows improved in the northern part, extreme highs increased slightly in some areas and there were substantial improvements in hydroperiod. Part of WCA-2B is approaching NSM-like conditions; the rest is still outside the NSM envelope.

- Eastern WCA-3A: General improvement in extreme high water conditions, particularly the area east of the Miami Canal. South of Alligator Alley, high water conditions are still poor. Extreme low water conditions did not change. The area is still outside the NSM envelope for both high and low water extremes.

- WCA-3B: High water conditions worsened. In the west, they are worse than the 1995 base, in the east they are worse than both bases. Both the frequency and depths of high events are far outside the NSM envelope for any NSM landscape. This problem must be resolved.

D-E.2.7 Pennsuco

- Both water levels and hydroperiods worsened relative to D13R. Water levels in the Pennsuco increased sufficiently higher to present a threat to tree islands.

D-E.2.8 Biscayne Bay

- An additional 77,000 acre feet/year of water was sent to Biscayne Bay, greatly improving conditions. Flows could be balanced better between parts of the bay but there is obviously the flexibility within the plan to do so.

- With some minor redirection of wet season flows between Central and South Biscayne Bay, D13R4 could meet targets in Central and South Biscayne Bay without reuse water from the proposed South Miami-Dade coastal reuse facility.

D-E.2.9 Model Lands

- D13R4 slightly increases water levels in coastal wetlands, particularly east of U.S. 1 during the dry season.

D-E.2.10 Big Cypress

- No change from D13R. Some water that used to flow west toward Roberts Lake Strand under NSM conditions still tends to move east as it did in D13R, apparently because of topography differences between NSM and SFWMM in the jetport vicinity. This is not good, but not a major problem.

D-E.2.11 Southern Everglades

- D13R4 delivered 271,000 acre feet/year of "new" water to Everglades National Park and performance measures closely approached targets for Shark River Slough and the Florida Bay coastal basins and exceeded targets in Rockland Marl Marsh. More detailed AET analyses of D13R4 for the southern Everglades will be available the week ending January 29, 1999.

- Endorsement of D13R4 by the AET regarding benefits to the southern Everglades should be strongly conditional on reversing potentially damaging effects to WCA-2A and WCA-3B and on providing adequate water quality treatment during detailed design and modeling.

D-E.2.12 Endangered Species

- Preliminary analysis shows no change to Cape Sable Seaside Sparrow, maybe a slight improvement for eastern populations.

- Improved conditions for wood storks, crocodiles, and manatees.

- ATLSS modeling results may show some snail kite concerns.

D-E.2.13 Uncertainties

- The NSM topography in NE Shark River Slough is assumed to be the same as current topography, although recent data collected by EPA scientists indicate that substantial soil subsidence has occurred since the 1940's. This discrepancy in the topographic model very likely affects the depth targets for NESS. If the NSM topography were altered to have comparable soil subsidence assumptions for WCA-3B north of Tamiami Trail and NESS south of Tamiami Trail, then target depths in NESS would probably be shallower, less water will be needed to meet those targets, and excess depths in WCA-3B would be reduced.

D-E.3 FULL AET REPORT ON D13R4

D-E.3.1 Water Quality

D-E.3.1.1 Introduction

The Water Quality Sub-team of the Restudy AET met by teleconference on Wednesday, January 27, 1999 to review Scenario D13R4 and to discuss comments and recommendations on the new scenario to the AET and the Restudy Team. The following persons participated in the teleconference: Eric Hughes and Dan Scheidt (USEPA); Bill Walker (consultant, DOI); Ken Tarboton, Tom Fontaine, Max Day, Jeff Needle, Siaka Kone, Zhenquan Chen, and Maxine Cheeseman (SFWMD); Betty Grizzle (USFWS); Nancy Gassman (Broward Co. DNRP); Mike Zimmerman and Sarah Bellmund (ENP); Herb Zebuth and Eric Bush (FDEP); and, Jim Riley (USACE).

Scenario D13R4 captures additional stormwater runoff in developed areas of Palm Beach and Broward County canals currently discharging to tide in Alternative D13R (the alternative plan selected by the Restudy Team), diverting it to the Water Conservation Areas. The purpose of the scenario was to increase overland flows into Everglades National Park and surface water flows discharged to Biscayne Bay. To accomplish this, C-51 Canal, C-15, C-16, Hillsboro Canal, C-13 Canal, C-14 Canal, and North New River basin runoff is routed (via pumps and other structural modifications) to storage components created by Alternative D13R and discharged to WCA-2A, Biscayne Bay, and Everglades National Park. A more detailed description of Scenario D13R4 is accessible via the Restudy web site, www.restudy.org.

D-E.3.1.2 Performance Based Comments

The effects of Scenario D13R4 on phosphorus loads and concentrations in the Everglades Protection Area can be modeled with SFWMD's Everglades Water Quality (phosphorus) Model (EWQM); however, the model had not yet been run for the scenario at the time of this writing. It should be noted that one of the Water Quality Team's previously agreed upon performance indicators for the EWQM was structural phosphorus loads discharged into the Everglades Protection Area. To meet the water quality requirements of the Everglades Forever Act, structural discharges to the Everglades Protection Area for Restudy alternatives/scenarios are assumed to be at the default phosphorus concentration criterion in the EFA (10 ppb). Using the structural phosphorus load performance indicator, and considering that Scenario D13R creates a new discharge into WCA-2A (173,000 acre feet/year, 31-year average), Scenario D13R4 would rank lower (not as preferred) from a water quality perspective in terms of relative performance in WCA 2A compared to Alternative D13R. It should be further noted that the EWQM cannot simulate potential water quality impacts in urban areas east of the WCAs.

The Everglades Landscape Model (ELM) would also be useful for modeling water quality and ecological responses in WCA-2A.

An initial evaluation of Scenario D13R4 was conducted using water budget data from the SFWMM. 31-year average flow volumes at selected structures for the 2050 Base, Alternative D13R, and Scenario D13R4 are compared below:

Table 2
31-year Average Flow Volumes at Selected Structures

Structure(s)	50B	D13R	D13R4
Site 1 Res to WCA 2A	0	0	173
S144-145-146s		158	501
S140A	175	460	468
NLB to B Bay (comb.)	0	88	138
NLB to ENP	0	0	88
CLB to B Bay (comb.)	0	0	71
CLB to ENP	0	95	80

Legend/Notes:
1) All flow volumes indicated are 31-year averages, in k ac. ft.
2) S144-145-146s are existing structures discharging from WCA-2A into WCA-2B
3) S140A discharges into NW WCA-3A; wq treatment via ECP/Non-ECP facilities
4) NLB = North Lake Belt Storage Area
5) B Bay = Biscayne Bay
6) CLB = Central Lake Belt Storage Area
7) ENP = Everglades National Park

Using water quality data from the SFWMD and Palm Beach and Broward County monitoring programs, mean phosphorus concentrations were determined by Dr. William Walker using an urban land use model for the basins contributing runoff captured in Scenario D13R4. Mean phosphorus concentrations are summarized below:

Table 3.
Mean phosphorus concentrations

C-51 Basin	122 ppb
C-15 Basin	366 ppb
C-16 Basin	214 ppb
Hills. Basin	154 ppb
C-14 Basin	123 ppb
C-13 Basin	138 ppb
C-12 Basin	199 ppb
NNR Basin	43 ppb

The C-51, C-15, C-16, and Hillsboro basins contribute runoff to be stored in the Palm Beach Agricultural Reserve and Site 1 water storage areas/STAs. The combined flow-weighted mean concentration of phosphorus was calculated to be 166 ppb.

The C-14, C-13, C-12, and North New River basins contribute runoff to be stored in the North and Central Lake Belt water storage areas/STAs. The combined flow-weighted mean phosphorus concentration was calculated to be 80 ppb.

STA sizes necessary to treat runoff to an interim target phosphorus concentration of 50 ppb were calculated for the Site 1/WCA-2A and Lake Belt discharges using the above combined flow-weighted mean phosphorus concentrations. Calculations were performed by Siaka Kone, SFWMD. Using the settling rate constant of 10.2 m/yr from the conceptual design for the Everglades Construction Project, the following STA sizes were calculated:

Table 4
Calculation of STA sizes

Site 1/Hillsboro STA	6,303 ac.
Lake Belt to ENP STA	1,238 ac.
Lake Belt to Biscayne Bay	1,083 ac

The sensitivity of STA size to enhanced STA performance (increased phosphorus settling rate constant) was also checked. Increasing the settling rate reduces the calculated area requirements for STAs.

Water quality data for contaminants other than phosphorus in Broward County surface waters (Hillsboro, C-14, C-13, C-11 basins) were also reviewed. Data summaries were provided by Dr. Nancy Gassman, Broward County DNRP. Mean dissolved oxygen levels were occasionally recorded below the State of Florida criterion (5.0 mg/l) and the Broward County criterion (4.0 mg/l). In addition to elevated concentrations of phosphorus, mean total nitrogen values occasionally exceeded the Broward County standard of 1.5 mg/l (there is no numeric criterion for total nitrogen in state water quality standards). Fecal coliform bacteria concentrations were also found to be occasionally elevated above the Florida and Broward County maximum concentration criterion (800-colonies/100 ml). Specific conductance at freshwater sites was also found to occasionally exceed the State of Florida Class III criterion (1275 u mhos/cm). Several trace metals have also been detected, including: arsenic, cadmium, chromium, copper, iron, lead, selenium, and zinc.

In sampling work conducted in 1997 and 1998, the following pesticides were also detected in Broward County surface waters: atrazine, diazanon, simazine, malathion, and ethion (BCDNRP 1999, draft).

D-E.3.1.3 Performance-Based Recommendations

None at this time; Scenario D13R4 was created to test the flexibility of the preferred alternative (Alternative D13R) to deliver increase flow volumes to Everglades National Park and Biscayne Bay. The Water Quality Subteam has identified a number of issues of concern (see Section IV below) which should be further addressed if the Restudy recommended plan was modified to perform as modeled in Scenario D13R4.

D-E.3.1.4 Water Quality Subteam Issues

1. Restudy components must meet state and tribal water quality standards, as appropriate. In particular, increased flows to the Everglades Protection Area must meet the yet-to-be-established Phase 2 numeric phosphorus criterion (default concentration = 10 ppb). The technology best suited to achieve the Phase 2 phosphorus criterion has not yet been determined. Calculations performed to evaluate Scenario D13R4 indicate that the proposed treatment area size for the Site 1 STA (2,160 ac.) is not sufficient to meet interim phosphorus treatment requirements (to achieve 50 ppb, 6,303 ac. is required) for discharges to WCA-2A, let alone Phase 2 treatment requirements.

2. In addition to phosphorus, several other pollutants have been identified in the urban runoff to be captured, stored, treated, and discharged to WCA-2A, ENP, and Biscayne Bay. In some of the developed basins/sub-basins to be backpumped, there is minimal potential to retrofit those areas with standard stormwater BMPs (e.g., detention/retention, vegetative filters, etc.). Reduction of pollutant loads via stormwater BMPs may be problematic.

3. The treatment efficacy of STAs for some of the constituents of urban runoff are unknown, and surface water quality criteria have not been developed for some of the pollutants identified. The long-term cumulative effects and ecological risk of discharging treating urban runoff containing small concentrations of pollutants to natural systems must be evaluated fully as part of future planning and design efforts associated with Scenario D13R4 and subsequent alternatives that may involve the use of urban stormwater runoff as a source of water to the natural system.

4. Diverting urban runoff for storage and backpumping to the Everglades or redirecting runoff for discharge to Biscayne Bay may have a deleterious effect on existing downstream water bodies in Palm Beach and Broward Counties by reducing dilution effects. According to FDEP's 1998 Section 303(d) list of water bodies not meeting water quality standards, there are several water bodies in Palm Beach and Broward Counties not supporting designated uses (Class III waters). Diversion of runoff, especially relatively clean runoff, may result in degradation of water quality in downstream areas. Furthermore, backpumping of the C-13 and C-14 Canals may degrade water quality in western portions of the canals by bringing in water of lower water quality from the east. It should also be noted that the Broward County data reviewed are from quarterly sampling activities; stormwater

runoff captured during and subsequent to storm events is likely to be of poorer quality containing first flush contaminants.

5. Scenario D13R4 creates a new point source discharge into the WCA-2A. This is not a desirable condition from a water quality perspective, as pollutants (and ecological responses) are concentrated within the zone of influence of the point source discharge. If pursued, a spreader swale or other mechanism should be designed to create overland flow conditions.

6. Scenario D13R4 increases the volume of water discharged to WCA-3A via the modified S140 pump station (Component RR4; see Table 1). Although it is understood that the upstream sources of the S-140 flows involve ECP/Non-ECP facilities, if subsequent planning and design work indicates that the proposed scenario creates performance deficiencies in those facilities, modifications of those treatment facilities would be necessary to accommodate increased flows while meeting water quality standards for discharges to the Everglades Protection Area.

7. The operations description for Scenario D13R4 indicates that urban runoff stored in the deep impoundment area at Site 1 will be injected via ASR facilities proposed for that component (Component M). Water quality data reviewed to date show multiple violations of surface water quality criteria, including the presence of pesticides. Underground injection control (UIC) regulations require that drinking water standards must be met prior to injection into underground sources of drinking water. Considering the unknown efficacy of conventional STAs to treat all contaminants that may be present in urban runoff to drinking water standards, regulatory approval of ASR as proposed would be difficult under current UIC regulations.

8. Everglades National Park and Biscayne Bay are Outstanding Florida Waters (OFWs) pursuant to Florida Administrative Code rule 62-302. OFWs are subject to an anti-degradation requirement based on conditions at the time of OFW designation. Discharges of treated urban runoff containing minute concentrations of pollutants may conflict with OFW discharge regulatory criteria.

9. The settlement agreement to the federal Everglades lawsuit sets phosphorus concentration limits for Everglades National Park at Shark River Slough and Taylor Slough/Coastal Basins and defines a compliance determination methodology. Operations as proposed for Scenario D13R4 may necessitate modifications to the compliance determination methodology.

10. Scenario D13R4 creates a 343.0 k ac. ft./yr. (31-year average; see Table 1 in Section II, above) flow volume increase through the S-144-145-146 structures complex, which discharge flows from WCA-2A to 2B. The long-term cumulative effects and ecological response of a flow increase of this magnitude must be evaluated fully as part of future planning and design efforts associated with Scenario D13R4. Also, it should be noted that the S-144-145-146 structures are

governed by the Non-ECP discharge structures requirements of the EFA; schedules and strategies developed under the EFA to assure that water quality standards in the EPA are met may have to be modified to account for increased flows in this location.

D-E.3.1.5 General Recommendations

1. If Scenario D13R4 or other alternatives that involve the use of urban stormwater runoff as a source of water for the natural system are to be pursued further, conceptual treatment area sizes should be increased to provide adequate treatment capacity per standard design practices. Additional contingencies (land area requirements, construction and operation costs) should be included in future planning and design actions to assure that EFA Phase 2 treatment requirements will be met for discharges to WCA-2A and Everglades National Park.

2. Alternative routing and treatment facilities to deliver increased overland flows to Everglades National Park and surface water flows to Biscayne Bay should be considered.

3. The Everglades Water Quality and Everglades Landscape Models should be run to compare water quality and ecological responses of Scenario D13R4 to Future Base and Alternative D13R simulated conditions (and other alternatives which involve the use of urban stormwater runoff as a source of water for the natural system) to Future Base and Alternative D13R simulated conditions. A subsequent evaluation should then be conducted by the Water Quality Team.

4. Local monitoring programs should be utilized to provide additional information for refining treatment technologies and the sizes of treatment areas necessary to reduce concentrations of pollutants in future detailed planning and design work.

5. Water and habitat quality impacts to natural areas east of the WCAs should also be investigated for those basins acting as sources of runoff.

D-E.3.2 Total System

D-E.3.2.1 Fragmentation Performance Measure

In D13R4, the number of miles of canals and levees stayed the same as in D13R. This performance measure is based on the artificial structures within the Everglades Protection Area, Rotenberger and Holey Land Wildlife Management Areas, Big Cypress National Preserve because these structures affect natural resources more so than those found within the urban or agricultural area. Any additional structures constructed as part of D13R4 would be located outside the natural system so they were not included in this measure.

Table 5
Miles of Canals and Levees Affecting Natural Areas

	1995 Base	2050 Base	D13R	D13R4	1995 Base – D13R4
Miles of Canals	330	311	184	184	-146
Miles of Levees	400	400	318	318	-82

D-E.3.2.2 Continuity Performance Measure

Hydropattern Comparison Across Barriers: The overall score for Alternative D13R for the differences in water levels across barriers or transects was 0.6 for all eight transects including Loxahatchee NWR (WCA-1) and the remaining barrier between WCA-2 and WCA-3. Alternative D13R4's score was also 0.6. The score remains relatively low because the system is not completely decompartmentalized.

Table 6
Continuity: Water level differences across barriers compared to NSM

	1995 Base	2050 Base	D13R	D13R4
LNWR/WCA2	0.0	0.0	0.0	0.0
WCA2-3	0.0	0.0	0.0	0.0
Miami Canal North	0.1	0.4	0.5	0.5
Miami Canal South	1.0	1.0	1.0	1.0
L-67	0.0	0.1	0.2	0.2
Tamiami Trail West	0.0	0.4	1.0	1.0
Tamiami Trail East	0.5	0.7	1.0	1.0
L-28	0.6	0.9	1.0	1.0
Average 3-9	0.4	0.6	0.8	0.8
Average 1-8	0.3	0.4	0.6	0.6

D-E.3.2.3 Sheetflow Performance Measure

Average annual overland flow volumes across a variety of transects showed both improvements and reductions in flow between D13R and D13R4 but the final overall score improved from 0.7 to 0.8, if L-67 was included; both scores were 0.9 if L-67 was excluded. Improvements were seen in dry season flows across T-8, the transect across eastern Alligator Alley, and both wet and dry season flows westward across T-21 Shark River Slough and T-18, eastern Tamiami Trail. Dry season flows were reduced across T-25 in the eastern Big Cypress and T-7 in Alligator Alley west. The biggest differences were seen across two transects not used in earlier analyses because no changes had been seen before. Flows across T-19, the north-south transect just west of L-31N and T-20, the L-67 extension, reversed direction to their normal westward flow and volumes increased greatly. Between D13R and D13R4, scores for T-19, west of L-31N improved from (dry season) 0.6 to 0.9 and (wet season) 0.5 to 1.0. T-20 (L-67 extension) scores rose from (dry season) 0.7 to 0.8 and (wet season) 0.7 to 0.9.

Table 7
Flow volumes across transects

	1995 Base	2050 Base	D13R	D13R4
Big Cypress Group	0.8	0.3	0.9	0.9
Central Everglades	0.8	0.3	0.8	0.8
Southern Everglades	0.8	0.3	0.9	1.0
Tamiami Trail Group	0.6	0.2	0.9	0.9
L-67	0.1	0.0	0.1	0.1
Score (avg. of all)	0.6	0.2	0.7	0.8
Score (w/o L-67)	0.6	0.3	0.9	0.9
East ENP (new)			0.6	0.9

D-E.3.3 Lake Okeechobee

D-E.3.3.1 1995 Base

Under the revised 1995 Base, hydrologic conditions are not optimal for the lake ecosystem, in terms of the frequency of extreme high and low lake stage events.

The lake experiences 3 events per decade (on average) in which stages fall below 11 ft, a low water depth at which nearly all of the littoral zone is dry and unsuitable as habitat for fish and other aquatic biota. This equates to a score of 0.4, reflecting poor conditions from the standpoint of protecting ecosystem health. Prolonged moderate low lake stages (<12 ft for > 1 year) occur at a frequency of 1 in 10 years, giving a score of 0.9, indicating good conditions for ecosystem health. Extreme high lake stages (>17 ft), which can cause wind and wave damage to near-shore plant communities and transport nutrients into the pristine littoral zone, occur at a frequency of 2 in 10 years, giving a score of 0.7, indicating moderate conditions. Prolonged moderate high lake stages (>15 ft for > 1 year), which harm the ecosystem through a variety of mechanisms (reduced light penetration, loss of benthic plants, increased circulation of nutrient rich water to near-littoral regions) occur at a frequency of 2 in 10 years. This gives a score of 0.7, again indicating moderate conditions. Spring (January – May) lake level recessions (from 15 to 12 ft), considered beneficial to various ecosystem components, occur only twice per decade (on average). This is considered to be too infrequent to support a healthy littoral zone. The performance measure receives a score of 0.

Overall, the 1995 base condition receives a score of 0.6, indicating conditions that are not suitable for long-term support of a healthy lake ecosystem.

D-E.3.3.2 2050 Base

Conditions worsen for Lake Okeechobee under the 2050 Base, in regard to an increased frequency of harmful low water events caused by greater regional demands on the lake. However, there are fewer harmful high water events under this base condition than under the 1995 Base.

The lake experiences 4 events per decade (on average) in which stages fall below 11 ft. This equates to a score of 0, reflecting a high likelihood of severe harm to the ecosystem and its values. Prolonged moderate low lake stages (<12 ft for > 1 year) occur at a 2 in 10 year frequency, giving a score of 0.7, reflecting moderate conditions. Extreme high lake stages (>17 ft) and prolonged moderate high lake stages (>15 ft for >1 year) occur at frequencies of 1 in 10 and 2 in 10 years, respectively, giving scores of 0.9 (good) and 0.7 (moderate). As in the 1995 base, spring lake level recessions occur only once every five years, and the associated performance measure receives a score of 0, reflecting harmful conditions for the littoral zone.

Overall, the 2050 base condition receives a score of 0.5, indicating conditions that are detrimental to the long-term health of the lake ecosystem.

D-E.3.3.3 Alternatives D13R, D13R2 and D13R4

The hydrologic conditions experienced by Lake Okeechobee are nearly identical (from the standpoint of ecological effects) for planning alternatives D13R, D13R2 and D13R4. All three represent substantial improvements in comparison with the 1995 and 2050 base conditions. Over 70% of the stage duration curve falls within the restoration goal of a 12 to 15 ft depth range under these alternative plans, as compared with only 50% under the 1995 Base and 45% under the 2050 Base.

Under alternatives D13R, D13R2 and D13R4, extreme low lake stage events (<11 ft) occur at a frequency of 1 in 10 years (on average), giving a score of 0.9 (good). Prolonged moderate low lake stages (<12 ft for >1 year) occur less often than 1 in 10 years, giving a score of 1.0 (excellent). Prolonged moderate high lake stages (>15 ft for >1 year) and extreme high lake stages (>17 ft) occur at frequencies of 1 in 10 years. This gives scores of 0.9 (good) for these performance measures. There are, on average, 3 spring recession events per decade under these alternatives, and this equates to a score of 0.

The overall score for alternatives D13R, D13R2 and D13R4 are 0.8, indicating moderate to good conditions.

D-E.3.3.4 Conclusions

The 2050 Base, with increased regional demands on the lake, and without features of the Restudy, has two effects on Lake Okeechobee: (1) it worsens conditions in regard to more frequent low stage events; and (2) it improves conditions in terms of fewer extreme high stage events. This does not represent a balanced improvement for the ecosystem, which is what the Restudy is striving to achieve.

Alternatives D13R, D13R2 and D13R4, which are nearly identical in performance, represent marked improvements in hydrologic conditions for the lake. Hydrologic conditions in the lake not only are improved over the 2050 Base, but also are improved relative to the 1995 Base; this means that alternatives D13R, D13R2 and D13R4 may be viewed as progress towards restoration.

At this point, it should be reiterated that the improved scores under the D13R alternatives are clearly a function of extensive use of ASR to move water out of and into the lake during periods of high and low lake stages, respectively.. If this technology proves to be infeasible, hydrologic benefits to the lake observed in the alternatives may be substantially reduced. A previous scenario involving removal of Lake Okeechobee ASR resulted in substantially inferior performance, both in terms of extreme high and low lake stage events.

Table 8
Scores for the priority
hydrologic performance measures
for Lake Okeechobee

Performance Measure	**1995 Base**		**2050 Base**		**Alt D13R**		**Alt D13R2**		**Alt D13R4**	
	#	score	#	score	#	score	#	score	#	score
<11 ft	3	0.4	4	0.0	1	0.9	1	0.9	1	0.9
<12 ft / >1 yr	1	0.9	2	0.7	0	1.0	0	1.0	0	1.0
>15 ft / >1 yr	2	0.7	1	0.9	1	0.9	1	0.9	1	0.9
>17 ft	2	0.7	2	0.7	1	0.9	1	0.9	1	0.9
Sp. Recession	2	0.0	2	0.0	3	0.0	3	0.0	3	0.0
Weighted CSI	0.6		0.5		0.8		0.8		0.8	

values indicate the number of events per decade (average for 30-yr period of record); scores are calculated as described in the document entitled "Priority Hydrologic Performance Measures for Lake Okeechobee," and the weighted CSI value is calculated using the Lake Okeechobee ROGEM equation.

D-E.3.4 Lake Okeechobee Service Area

This section presents the Lake Okeechobee Service Area (LOSA) sub-team evaluation and scoring results for Restudy Alternative D13R4.

First, results of earlier evaluations are summarized to set a context for the evaluation of D13R4. The LOSA sub-team in its previous reports indicated that Alternatives A, C and D come close to meeting the water supply level of service goal and are judged to have good performance, with Alternative D being clearly the best performer. When the LOSA sub-team evaluated Alternative D13R, it found that the modifications to Alternative D13 that resulted in Alternative D13R had no significant effect on the good performance of Alternative D with respect to Lake Okeechobee Service Area water supply.

The principal goal utilized by the LOSA sub-team was that the alternatives should be able to meet all demands in a 1 in 10-year drought. It was also agreed that the best available indicator that this was being done would be if the number of years with water shortage restrictions were not more than 3 in the simulation period. In developing the count of years with water restrictions, certain events with very minor restrictions were not counted. None of the alternatives reach this goal (3 or less events) but with 5 events Alternatives D, D13R and D13R4 all come close.

The strong performance of Alternatives A, C and D is further evidenced when the duration (total months of supply side management with restrictions greater than 18,000 acre feet/year) of the water restriction periods is considered. For Alternative D, LOSA is under restrictions only 9 months in the simulation period, while for Alternatives D13R and D13R4 there are only 8 months of restrictions.

The same scoring analysis, which was completed for earlier alternatives, was also completed for Alternative D13R4. The reader is referred to the previous evaluations for explanations of the rationale and procedure for the scoring analysis. The scoring results for Alternatives D, D13R and D13R4 are provided in Table 9 below. Attachments A and B detail the calculations presented in Table 9. The data in the table indicate that all three alternatives score essentially the same. Alternatives D13R and D13R4 show a slightly better score because they each have one less month of water shortage than does Alternative D.

Table 9
LOSA Water Supply Scoring Results for Alternatives D, D13R and D13R4

Alternative	Frequency Score	Duration/ Severity Score	Combined Score
Alternative D	0.926	0.853	0.890
Alternative D13R	0.926	0.862	0.894
Alternative D13R4	0.926	0.862	0.894

D-E.3.4.1 Attachment A

Calculation of Frequency Scores

Alternative	Number of Water Years with Restrictions	Frequency Score = (30 – Years with Restrictions)/27
Alternative D	5	0.926
Alternative D13R	5	0.926
Alternative D13R4	5	0.926

D-E.3.4.2 Attachment B

Calculation of Duration/Severity Scores

Note that the scaled duration/severity score is calculated using the following formula:

Scaled duration/severity score = 1 – (Combined Duration Severity Score for the Alternative÷Combined Duration Severity Score for the Worst Alternative)= 1 – (Combined Duration Severity Score for the Alternative÷109).

Alternative D

Water Years With SSM Cutbacks	Highest Monthly Cutback	Severity Score	Duration Score	Combined Duration/ Severity Score = Severity Score + Duration Score
1981	168,350	4	4	8
1982	95,040	2	3	5
1990	39,820	1	2	3
Total Combined Duration/Severity Score				16
Scaled Duration/Severity Score				.853

Alternative D13R

Water Years With SSM Cutbacks	Highest Monthly Cutback	Severity Score	Duration Score	Combined Duration/ Severity Score = Severity Score + Duration Score
1981	167,720	4	4	8
1982	95,140	2	3	5
1990	39,680	1	1	2
Total Combined Duration/Severity Score				15
Scaled Duration/Severity Score				.862

Alternative D13R4

Water Years With SSM Cutbacks	Highest Monthly Cutback	Severity Score	Duration Score	Combined Duration/ Severity Score = Severity Score + Duration Score
1981	166,570	4	4	8
1982	98,050	2	3	5
1990	36,350	1	1	2
Total Combined Duration/Severity Score				15
Scaled Duration/Severity Score				.862

D-E.3.5 Caloosahatchee Estuary

Performance Measure: The number of times salinity envelope criteria were not met for the Caloosahatchee Estuary.
Goal: A base flow of 300 cfs is needed to maintain appropriate salinities.
Performance: The number of minimum flow violations is well below the target value and the same as D13R.

Performance Measure: The number of times high discharge criteria (mean monthly flow > 2,800 and 4,500 cfs) were exceeded for the Caloosahatchee Estuary.
Performance: The number of high flow violations is well below the target value and the same as D13R.

Performance Measure: Regulatory releases from Lake Okeechobee.
Goal: None are desired.
Note: D13R4 had one regulatory release.

D-E.3.5.1 Recommendations

Overall, D13R4 is the same as D13R in the Caloosahatchee basin.

D-E.3.6 St. Lucie Estuary

Performance Measure: Number of times salinity envelope criteria were not met for the St. Lucie Estuary.
Goal: A base flow of 350 cfs is needed to maintain appropriate salinities.
Performance: D13R4 is the same as D13R and the base flow target has been met.

Performance Measure: Number of times high discharge criteria (mean monthly flow > 1,600 & 2,500 cfs) were exceeded for the St. Lucie Estuary.
Goal: No regulatory releases, and reduction in high discharges for > 14 days.

D13R4 is the same as D13R, except that D13R4 has one more >1600 cfs violation. In both D13R and D13R4, the targets are almost met for that estuary (See the St. Lucie issue paper for the AET).

D-E.3.6.1 Recommendations

Detailed planning in the Indian River Lagoon Feasibility Study should be able to help make any additional improvements.

D-E.3.7 Lake Worth Lagoon

Performance Measure: Wet/Dry Season Average Flows Discharged to Lake Worth through S-40, S-41 & S-155 for the 31-year simulation.
Goal: To meet target flows to the Lake Worth Lagoon (0 - 500 cfs).

Performance: D13R4 is greatly improved over D13R and is the best plan so far. Much of the flow to the Lake Worth Lagoon was captured and sent south. The number of times the flow is >500 cfs decreased from 96 to 22 events in D13R4.

D-E.3.8 Northern and Central Everglades

D-E.3.8.1 Loxahatchee NWR (Indicator Regions 26 and 27)

Average annual hydroperiods in both indicator regions 26 and 27 are within 1% of target values defined by the 1995 Base and closely match Alternative D13R results. Compared to Alternative D13R, the mean inundation duration in Alternative D13R4 decreases slightly in north LNWR according to the performance of Indicator Region 27 (96 weeks in Alternative D13R compared to 85 weeks in Alternative D13R4) but the number of events increases (16 events in D13R, 18 events in D13R4). Inundation duration and number of events in indicator region 26 (south LNWR) exactly match Alternative D13R results.

Average annual duration of extreme low water events remains at 0% for both indicator regions meeting 1995 Base target values.

Extreme high water performance in Alternative D13R4 closely matches Alternative D13R. As stated in previous alternative evaluation summaries for this region, there remains uncertainty about the effect of high water on tree islands in southern LNWR. However, alternative D13R4 conforms overall to current hydrologic management objectives for the refuge.

D-E.3.8.2 Holey Land and Rotenberger WMAs

This region performs identically to Alternative D13R.

D-E.3.8.3 WCA-2A

Southern WCA-2A developed a problem with extreme high water under the D13R4 scenario. In Indicator Region 24 there are 52 weeks of depths greater than

2.5 ft over the 31 year period of record, compared with 18 weeks under D13R, 9 under the 2050 Base, 3 under the 1995 Base, and zero under NSM.

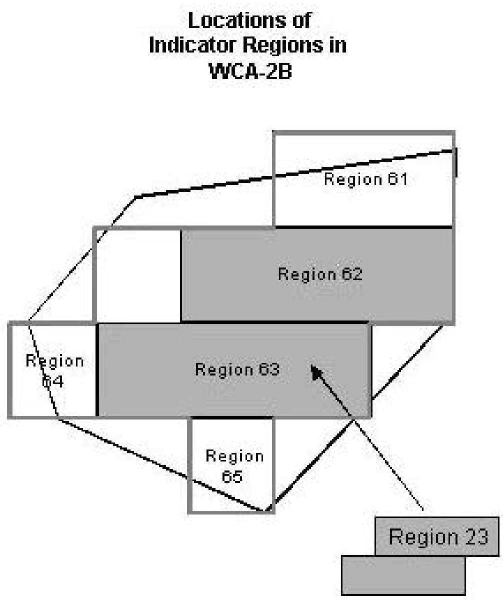
Southern WCA-2A had an excess of dry-downs to more than 1.0 ft below ground in D13R (12 events occupying 5% of time). It was hoped that discharges into WCA-2A from the Site 1 facility would alleviate this problem in D13R4. Unfortunately, flows from Site 1 are largely during the wet season and lead to increased high water, without alleviating the low water problem.

D-E.3.8.4 WCA-2B

The frequencies of extreme high and low water in Indicator Region 23 are very similar in D13R4 and D13R. However, when Indicator Region 23 is split into two separate indicator regions, improvements are seen by way of a lower frequency of extreme low water in the northern portions of the WCA. "New" Indicator Region 62 (Fig 1), which consists of the northern three cells of Indicator Region 23, shows a reduction in the frequency of depths more than 1.0 ft below ground, from 13% in D13R to 9% of time in D13R4. Although there is a slight increase in the frequency of extreme high water compared to D13 (5% vs. 3%), this is accompanied by a substantial improvement in hydroperiod, from 59% in D13R to 79% in D13R4. Overall, Indicator Region 62 has reduced low water compared to the 1995 Base and reduced high water compared to the 2050 Base. This area may be approaching conditions that are "NSM-like" for a sawgrass plains type of landscape, but the frequency of extreme low water is still of concern.

"New" Indicator Region 63, which occupies the southern and less-elevated part of Indicator Region 23 (Fig 1), exhibits a lower frequency of depths greater than 2.5 ft compared to D13R (27% vs. 33% of time). Both D13R and D13R4 are substantial improvements over the 1995 and 2050 Bases for extreme high water but they remain outside the range of NSM values for high water frequencies in the remnant peat landscape.

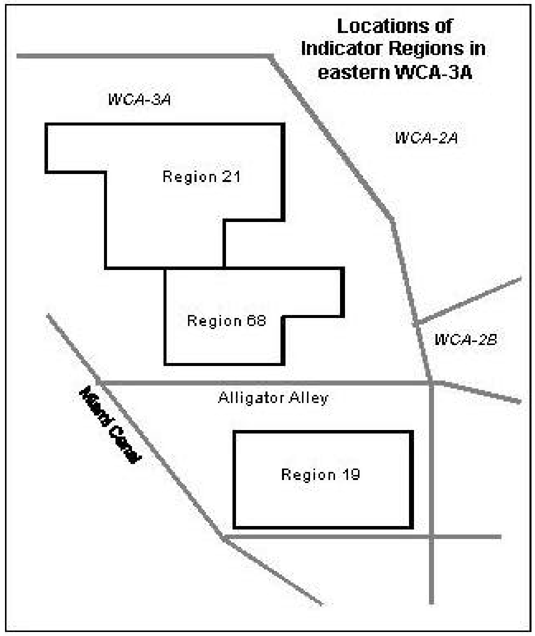
Figure 1



D-E.3.8.5 Eastern and Northeastern WCA-3A

The overall frequency of extreme high water in eastern and northeastern WCA-3A is reduced relative to D13R. In NE WCA-3A (Indicator Region 21), extreme high water is one-third as frequent in D13R4 as in D13R (2 vs. 6 events, occupying 1% rather than 3% of time); D13R4 is about the same as the 1995 and 2050 Bases (marginally better), whereas D13R had more frequent extreme high water than either Base. In Eastern WCA-3A (Indicator Region19), the frequency of depths greater than 2.5 ft is reduced from 19% of time in D13R to 15% of time in D13R4; both models had less extreme high water than the 1995 Base but more than the 2050 Base. In between these two indicator regions, in "new" Indicator Region 68 (Fig 2), trends are similar to those seen in Indicator Region19 although there is a much lower absolute frequency of extreme high water. When compared with NSM, Indicator Region 21 is similar to target values, but Indicator Regions 19 and 68 are not.

Figure 2



Extreme low water in northeastern WCA-3A (Indicator Region 21) is not improved in D13R4 compared to D13R, but is still slightly worse than the 2050 Base conditions.

Overall, performance is improved within WCA-3A east of the Miami Canal, but the area south of Alligator Alley still remains far from NSM target values for extreme high water.

D-E.3.8.6 WCA-3B

The frequency of extreme high water in WCA-3B increased in D13R4 compared to D13R, for all four indicator regions evaluated. Indicator Region 15 in western WCA-3B increased from five high water events under D13R (3% of time) to 10 high water events under D13R4 (5% of time); this is more extreme than the 1995 Base (1% high water) and similar to the 2050 Base (5% high water). Indicator Region 16 in eastern WCA-3B has an increase from 13 high water events in D13R (5% of time) to 19 high water events in D13R4 (11% of time). This is more extreme than either the 1995 or 2050 bases (3% and 8% high water, respectively). It is also a high frequency of extreme depths than that seen under NSM for any indicator regions within the remnant peat landscape. Two “new” indicator regions that were delineated in northern WCA-3B (Indicator Regions 22 and 27) also show increases in the frequency of extreme high water in D13R4 compared with D13R.

D-E.3.8.7 Pennsuco Wetlands

Both water levels and hydroperiods worsened relative to D13R. D13R4 resulted in a substantial increase in the number of high water events over those reported for both bases and D13R. In addition, the average duration of flooding in Pennsuco North has more than doubled relative to NSM projections and is more than 4 times longer than either base condition. Water levels in the Pennsuco increased relative to D13R and were sufficiently higher in D13R4 to present a threat to tree island resources in the basin.

*Pennsuco North Stage Duration Curve: The D13R4 curve is higher than the 1995 and 2050 Bases and higher than D13R. The D13R4 curve shows slightly higher water levels than D13R during most of the period of record, but water levels are reduced relative to D13R2. The high water level exceedance count shows a strong increase in the number of weeks where the high water target is exceeded for D13R2 (147 weeks) and D13R4 (196 weeks) relative to D13R (23 weeks). The stage hydrographs show that several of these high water events are of sufficient duration to cause possible flooding impacts to existing tree islands. Inundation pattern shows that there would be no drydown for most years in this basin if D13R4 were implemented as described. D13R hydroperiod and hydropattern would be preferred for this region.

*Pennsuco South Stage Duration Curve: Same comments as Pennsuco North, but the number of weeks that the high water target is exceeded is 118 weeks for D13R2, 161 weeks for D13R4, and 18 weeks for D13R.

D-E.3.8.8 Overall Northern and Central Everglades

There is some improvement in two areas – eastern/northeastern WCA-3A and WCA-2B – that were deficient under D13R; however, these areas still deviate from target conditions. Other areas, notably southern WCA-2A and WCA-3B, deviate further from targets than under D13R. Overall, substantial regions of the WCA system fall outside the range of performance seen in NSM for indicator regions in the peat landscape. D13R4 performance in southern and south central WCA-3A was relatively similar to D13R.

D-E.3.9 Southern Everglades

Alternative D13R provides substantial improvement toward the attainment of restoration targets for the southern Everglades in comparison to base conditions and Alternative D. However, questions remain about D13R regarding its adequacy in achieving restoration in three areas of the southern Everglades. Those areas are annual flow volumes down Shark River Slough, related salinity regimes in the coastal basins of Florida Bay, and duration of uninterrupted flooding in the rockland marl marsh. The additional hydrologic modeling that led to D13R4 determines how much performance in the three areas can be improved by capturing runoff that is presently lost to tide along the lower east coast. The modeling exercise captures runoff that does not appear necessary to prevent saltwater intrusion or to sustain the water demands of the lower east coast service areas. It routes that water either through the water conservation areas or through the eastern flow corridor for delivery either to northeast Shark River Slough or to Biscayne Bay.

Two major concerns that surface during the D13R4 modeling exercise are water quality and water conservation area hydrologic parameters. For the first time in alternative plan analyses for the Restudy, urban runoff water is delivered to the natural system. While provisions are made in the modeling to treat the questionable water quality of that urban runoff, uncertainty is acknowledged regarding both the adequacy of that treatment and the level of treatment that will be necessary before the delivery of such water to the natural system. The other concern is that efforts to correct the problems in the southern Everglades exacerbate ecologically damaging high water conditions in portions of the water conservation areas. Both of these problems must be addressed in detailed design before the features modeled in D13R4 can be implemented.

The following analysis focuses on the benefits of D13R4 regarding the three problem areas in the southern Everglades. The many other performance measures that have been analyzed in previous model runs are more cursorily examined to insure that D13R4 has not decreased performance in those areas.

D-E.3.9.1 Shark River Slough

D13R4 provides a mean annual flow volume of 1,258 acre feet down mid Shark River Slough, which represents a 166,000 acre foot annual average increase compared to D13R. The performance of D13R4 translates to 81% achievement of the NSN45F target of 1,561,100-acre feet/year, compared to 70% under D13R, 52% under 2050BSR, and 44% under 1995BSR.

The increased flow volume down Shark River Slough has no net effect on the number of dry events during the period of record in the slough indicator regions, compared to D13R, because most of the increased flow volume occurs during the wet season. Likewise, there is only slight improvement in the seasonal distribution of flows in an increase from 92% concordance with NSM45F in D13R to 94% in D13R4. Mean depth during periods of flooding shows a modest increase from a 77% match in D13R to an 83% match in D13R4.

D-E.3.9.2 Florida Bay Coastal Basins

The gains in Shark River Slough flow volume and water depth are reflected in water stages at the P-33 gage in the central slough. The stage at P-33 is correlated to salinity in the coastal basins of Florida Bay, in that P33 stage is indicative of freshwater heads throughout much of Everglades National Park that drive flow to the coastal basins. Stages equaling or exceeding 6.3 feet msl at P-33 indicate the avoidance of undesirable high-salinity events in the coastal basins. Stages of 6.3+ increase in frequency from 220 months in D13R to 235 months in D13R4 during the 31-year period of record. This represents a 91% achievement of the NSM45F target of 258 months, compared to 85% in D13R, 69% in 50BSR, and 48% in 95BSR. Stages equaling or exceeding 7.3 feet msl, indicate the attainment of desirable low-salinity events in the coastal basins. Stages of 7.3+ increase in frequency from 16 months in D13R to 23 months in D13R4 during the 31-year period of record. This represents a 77% achievement of the NSM45F target of 30 months compared to 53% in D13R, 7% in 2050BSR, and 23% in 1995BSR.

D-E.3.9.3 Rockland Marl Marsh

The gains in Shark River Slough flow volume also extend to the higher-elevation wetlands of the Rockland Marl Marsh to the east of the slough. The mean duration of uninterrupted flooding in the Rockland Marl Marsh increases from 30 weeks in D13R to 37 weeks in D13R4. The performance of D13R4 represents an84% achievement of the 44-week NSM45F target, compared to 68% in D13R, 52% in 2050BSR, and 27% in 1995BSR. Accompanying the increase in mean duration of flooding is a decrease in the mean duration of dry events from 21 weeks in D13R to 18 weeks in D13R4.

D-E.3.9.4 Conclusions for Southern Everglades

The hydrologic benefits to the southern Everglades of Alternative D13R can be increased if the features of model run D13R4 can be incorporated during the detailed modeling and design phases of the Restudy. Performance increased to greater than 80% of the NSM45F target in each of the three problem areas that were identified for the southern Everglades – Shark River Slough flow volume, Florida Bay coastal basin salinity regime, and Rockland Marl Marsh duration of uninterrupted flooding. The endorsement of the benefits of D13R4 in the southern Everglades is strongly conditional on addressing the water quality concerns and correcting the high-water conditions in the Water Conservation Areas during detailed modeling and design.

D-E.3.10 Lower East Coast Service Area

The Lower East Coast Service Area (LECSA) is divided into four service areas: North Palm Beach, and Service Areas 1, 2, and 3. The North Palm Beach Service Area extends from northern to central Palm Beach County, encompassing approximately one-third of the county and includes one primary canal, the C-17. Service Area 1 covers the remainder of Palm Beach County and a small portion of Broward County to just below the Hillsboro Canal. There are four primary canals that traverse the service area: C-51, C-16, C-12, and the Hillsboro Canal. Service Area 2 includes most of Broward County and a portion of Miami-Dade County. It extends south from the Hillsboro Basin to just south of the C-9, which lies in

Miami-Dade County. Four primary coastal canals extend through Service Area 2: C-14, C-13, North New River, and C-9. Service Area 3 includes the remainder of Miami-Dade County from the C-9 Basin south to near the tip of the peninsula. There are three primary coastal canals in Service Area 3: C-4, C-6 and C-2. Although the county boundaries extend west to the center of the state, the service areas only include those portions of the counties east of the protective levees.

D-E.3.10.1 Background: Water Supply

The performance measures used for the Lower East Coast to evaluate Restudy alternatives for water supply relate to the frequency and duration of water supply cutback events and the ability to maintain primary coastal canals. Water supply cutbacks are mandatory reductions imposed by the District on the LECSA utilities and general population to conserve existing water supplies when a shortage is imminent. Water supply cutback events usually occur during the dry season, when replenishment of stored water is limited.

During the dry season structural releases are periodically made from the Water Conservation Areas (WCAs) and Lake Okeechobee to maintain ground water levels and to minimize the possibility of saltwater intrusion along the coast. The Lower East Coast uses this water from the regional system to recharge secondary canal networks, wellfields and other recharge areas, and lakes. These ancillary systems are maintained by the local utilities to continue meeting public water supply demands. During the wet season and under normal conditions, rainfall and seepage account for the vast majority of recharge to the LECSA surface and ground water system that supplies this area.

During extended dry periods, Lake Okeechobee and the WCAs are important sources of surface water supply for large regions of South Florida. WCAs 1, 2A and 3A are the primary sources of supplemental surface water supply for the Lower East Coast Service Areas 1, 2, and 3, respectively. When water stored in the WCAs and Lake Okeechobee is scarce, for instance during a drought, the urban water supply demands are restricted (cut back) in order to conserve the remaining supplies in the regional system. Although the service areas are able to continue to meet some demands through local sources, all service areas are dependent on the WCAs and Lake Okeechobee to supplement surface water supply and support urban public water supply demands. This is true for all of the service areas except Northern Palm Beach Service Area, which relies on local supplies.

The availability of recharge water to the LECSA via surface or ground water through either seepage or structural flows from the regional system can be evaluated based on the surface water storage in Lake Okeechobee. The storage volume within the lake gives a more quantitative indicator that a water shortage condition may be approaching. The water supply cutbacks in the LECSA are based partly on the available surface water storage in Lake Okeechobee. However, the primary triggering mechanism for implementing the LECSA cutbacks is related to ground water levels within the LECSA.

Low ground water levels near the coast increase the vulnerability of the Biscayne aquifer to saltwater intrusion. Continuing to meet urban water demands may exacerbate ground water levels and therefore cutbacks are necessary when there is a threat to the resource. Low storage levels in the Lake Okeechobee at the beginning of the dry season are indicative of a prolonged storage problem that dictates when the cutbacks can be removed while low ground water levels indicate immediate problems within the LECSA. Either of these triggers, Lake Okeechobee or local ground water levels, can initiate a water supply cutback and are reflected in the ability to meet the 1-in-10 level of service water supply goal. Although regional water supplies or local ground water levels may rebound during the dry season, cutbacks are continued through the end of the dry season, May, to ensure protection of the Biscayne aquifer.

The availability of water from the regional system to recharge the LECSA via structural discharges can be evaluated based on the ability to maintain the primary coastal canals above their saltwater intrusion criteria. This third performance measure, maintaining the surface water levels and continuing their recharge functions, is critical to protecting the Biscayne aquifer from saltwater intrusion. However, it should be noted that saltwater intrusion could still occur even if the primary canals are maintained. Some areas along the salt front cannot be adequately recharged from the regional system to offset local demands on ground and surface waters or to abate saltwater intrusion. Local conditions and demands can contribute to the movement of the salt front as well by lowering ground water levels.

The primary coastal canal performance measure is indicative of the ability to meet the proposed criteria for minimum flows and levels for the Biscayne aquifer. Chapter 373, F.S. directs all of the water management districts to establish minimum flows and levels for surface waters and aquifers within their jurisdiction. The District will be proceeding with rule development for the minimum level criteria for the Biscayne aquifer in the near future. The minimum level criteria for the Biscayne aquifer was utilized in the SFWMM model to reflect future demands from the regional system.

The performance measures described herein rely upon a linear relationship between performance and the scores developed for comparative purposes. Only the 1-in-10 level of service performance measure was normalized. No weighting was applied to the performance measures since all were considered equally important to continue the functions of the Biscayne aquifer and other resources in the Lower East Coast.

D-E.3.10.2 Performance Measures and Indicators

Two performance measures and one performance indicator are analyzed for each service area. In Service Area 3, an additional performance indicator, Ability to maintain South Miami-Dade Canals, was analyzed. These performance measures were selected due to their ability to measure how the alternative performs in protecting the Biscayne aquifer and providing recharge to the aquifer for public water supply. These measures are indicative of how well the conceptual designs may perform together on a regional scale. Additional feasibility studies and detailed designs will need to be pursued prior to implementation of any of the components included in the Comprehensive Plan.

1) Ability to meet the 1-in-10 water supply planning goal: The frequency of water supply cutbacks is indicative of the reliability of regional and local water supplies through various weather and resource conditions. Water supplies in Lake Okeechobee supplement deliveries to the LECSA to maintain ground water levels to prevent saltwater intrusion near the coast. Public water supplies are reduced or cutback at the well field in response to low surface water levels in Lake Okeechobee or ground water levels near the coast. The planning goal is to find a balance between ability of the regional system to supplement recharge of the aquifer and meet the public water supply planning goal of a 1-in-10 year level of service in the lower east coast of Florida. The planning goal is in terms of the frequency of cutback events and is defined as no more than three cutback events, no more than seven months in duration over the period of record. A cutback event can begin in the fall and continue through the spring, therefore the maximum number of cutback events in the period of record is thirty. The score represents the number of cutback events during the period of record minus the three allowed events compared to the maximum number of years the 1-in-10 year level of service planning goal can be met. Alternatives that equaled or exceeded the goal, i.e. had three or less cutback events, scored 100% (no extra credit was given for exceeding the planning goal).

Score =[1 · ((# of cutback events · 3 years)/27 years)]100 = % of years goal met

2) Percentage of months not in a water supply cutback: The duration of water supply cutbacks is another characteristic of a drought event and is used as an indicator of the reliability of water supplies. The number of months of water supply cutbacks incurred in a service area capture the lengths of time urban demands are not met. The increased or decreased length of the cutback events is captured by counting the total number of months when the service area is in a water supply cutback, regardless of the severity of the cutback, as a percentage of the total number of months in the period of record. This percentage of time would be subtracted from one to reflect the improvement, increasing amount of time not in a water supply cutback, attributable to the alternative.

Score =[1 · ((# of months service area in cutback)/372 months)]100 = % of time in a cutback

3) Ability to maintain saltwater intrusion criteria: Maintaining the primary coastal canals above the saltwater intrusion criteria is critical to protecting the Biscayne aquifer from saltwater intrusion and is part of the proposed criteria for minimum flows and levels. Each Service Area includes several primary coastal canals that have saltwater intrusion criteria developed for them. In the SFWMM, the stage of the coastal canal is compared to the criteria on a daily basis. If the canal is unable to be maintained for a week, the event is counted towards the time the saltwater intrusion criteria was not met. All canals were weighted equally except in Service Area 3, where the C-6 and C-2 were weighted more than the C-4 due to their ability to provide wellfield recharge. The performance measure is reported as the percentage of time the canal stage is below the saltwater intrusion criterion, which is subtracted from one to report the percentage of time the canal is above the saltwater intrusion criterion.

Score = [1- % of time not able to maintain canals]100 = % of time able to maintain canals

4) Maintaining water levels in south Miami-Dade canals: At this time, saltwater intrusion criteria do not exist for the major canals in southern Miami-Dade County. However, it is important to evaluate water levels in these canals because encroachment of the salt front into the Biscayne aquifer has occurred previously in this area. Plus, major public water supply wellfields are located in southern Miami-Dade County. This area was evaluated by using the stage duration curves for the following structures: C-100A @ S-123, C-1 @ S-21, C-102 @ S-21A, and C-103 @ S-20F. The stage duration curves were used to evaluate the alternatives in two ways: 1) the distance by which an alternative's water level fails to reach two feet NGVD at the 90th percentile of the stage duration curve; and 2) the percentile at which an alternative's stage duration curve meets the 50th percentile of the 1995 Base stage duration curve.

In the first scenario, two feet NGVD was used for comparison in keeping with the Ghyben-Herzberg relationship which estimates that one foot of fresh water head is required to protect 40 feet of aquifer. The aquifer along the coast in southern Miami-Dade is approximately 80 feet that would require two feet of fresh water head. The 90th percentile of the stage duration curve was used since that percentile reflects lower stages of the dry season when the risk of saltwater intrusion is increased. The score is calculated from the distance of the base conditions and alternatives to the two feet NGVD on the stage duration curve. Alternatives that equaled or exceeded the target scored 100% (no extra credit was given for exceeding the target).

Score = [(2 - Distance/2)] x 100 = % of meeting 2 foot target

The second scenario used the 50th percentile of the 1995 Base to evaluate performance since it represents approximately the midpoint between the wet and dry seasons and can be viewed as "average conditions" for the 1995 Base. The score reflects the percentile at which a base condition or alternative meets or exceeds the water level at the 50th percentile of the 1995 Base. Saltwater encroachment has occurred in the period of record and, therefore, exceeding the 50th percentile is considered an improvement but may not prevent further encroachment.

The base conditions and alternative scores were determined by averaging the scores for the two scenarios.

D-E.3.10.3 Flood Protection

Flood protection is one of the authorized purposes of the Restudy and will be evaluated and addressed during the detailed design phase of the study. Due to the grid size and type of model used during the Restudy alternative evaluation process, the performance measures available for the Lower East Coast Service Area are of limited value for direct evaluation of an alternative's affect upon flood protection. However, one performance indicator is applicable for the southern Miami-Dade County agricultural areas in Service Area 3, stage duration curves, and is used in this evaluation.

D-E.3.10.4 Urban Areas East of the Protective Levee in the Lower East Coast

Flood protection should be improved or at least not degraded by the selected plan. In many instances, the alternatives have reduced or eliminated adverse impacts to flood control associated with the components selected in the urban areas of the Lower East Coast. The alternatives provide additional water storage capacity through water preserve areas, reservoirs and aquifer storage and recovery, reducing the maximum stages in the canals during large rainfall events.

The risk of flooding may be decreased with the additional storage components; however, it is difficult to discern the improvements at this point in the alternative evaluation. The model used to evaluate the effects of the components on regional hydrology is not conducive for evaluating storm and flood events. The model uses a daily time step; storm and flood events occur within hours. One-performance indicator gauges the change in peak stages compared to the 1995 Base on a regional basis. The primary drawback of this performance indicator is that it does not distinguish between ground and surface water levels.

After the final plan is selected, this performance indicator will be used to identify areas of potential decreased flood protection coupled with site specific information regarding flood prone areas. Information regarding existing flood prone areas will be gathered from District and USACE staff familiar with the Lower East Coast supplemented with interviews with local government officials and other who have technical input. These areas will be mapped using the SFWMM grid cell boundaries and will be identified by the appropriate basin. These identified areas will undergo further evaluation in subsequent feasibility reports to determine what actions are necessary. In addition, portions of the study area outside of the boundaries of the SFWMM grid will need to be evaluated for flooding impacts through a separate process as well.

D-E.3.10.5 Agricultural Area along the L-31N

One performance measure graphic was developed for use in six cells in the western areas of southern Miami-Dade County (Lower East Coast Service Area 3) to compare the relative performances of the different alternatives. It is labeled "end of the month stage duration curve 1983-1993", and compares an 11-year target stage duration curve to the 31-year stage duration curves representing the performances of the bases and alternatives. The relative comparison of an 11-year curve to a 31-year curve appeared to be appropriate for use at the higher stages, but did not compare as well at the mid to lower stages.

D-E.3.10.6 Scoring Procedures

Because the comparisons between the curves are most appropriate at the higher stages, it was decided to use the point where the stage duration curves intersect with the "10 % time equaled or exceeded" line on the graphs. For each of the six indicator cells, the difference between where an alternative or base curve intersects the 10 % line and where the target curve intersects the 10 % line is measured (in tenths of a foot).

Only the increases in stages relative to the target are included in the matrix. The actual differences are shown in the first half of the matrix, and are used in the alternative scoring methodology described below. If an alternative performance falls below the target (performance is better than the target), a score of 0 is given. This is shown in the second half of the matrix. The values for all the cells are summed and normalized so the final scores range between 0 and 1.

A second scoring methodology that gives credit for flood protection above the target was used for comparison. In order to normalize the alternatives' scores, five (5) was added to each sum so the final numbers were all positive. The resulting values are shown as an "alternative score".

D-E.3.10.7 Interpretation of Results

Using the first scoring methodology, alternatives D13R and D13R4. performed equally. There is no measurable difference between the stage duration curves at the 10% line. The operational changes that were implemented in the C-111 basin in all alternatives are thought to be the reason for this result.

In looking at the second scoring methodology where credit is given for an increase in flood protection in some of the northern cells, alternatives D13R and D13R4 perform equally well. Since exceeding the target line is a "bonus" and it only occurred in some of the cells, it's not recommended to base selection of a preferred alternative on these results. They are presented only for informational purposes.

Alternative D13R4 performed equally to Alternative D13R. There were no changes in operations in this area, so the performance did not change.

Table 10

	R10 C25	R13 C25	R15 C26	R17 C27	R19 C27	R20 C27	
Difference in stage in tenths of a foot							**Totals**

D-E.3.10.8 Other Issues

Reductions in discharges to tidal waters proposed in D13R4: Reductions in discharges to tidal waters may cause both water quality and natural area impacts in response to the lowering of the flushing rates. With reduced fresh water discharges to tide, groundwater (typically low in dissolved oxygen) will contribute a larger portion of the base flow of these tidal bodies of water. Also, with reduced flushing rates the headwaters may be more inclined to be biologically conditioned with a potentially high incidence of undesirable algal blooms. Within Broward County the contrast between the tidal portion of the Middle River (C-13), which has good water quality, with the North Fork of New River (C-12), which has continuing unsolved water quality problems, may be a good example of the result of reduced fresh water flow. In addition, with a decrease in fresh water discharges the salinity regimes of the downstream tidal water will increase. Examples are the C-10 canal and Intracoastal Waterway between Port Everglades and Haulover Inlet. Both are prone to hypersaline conditions because of little or no fresh water discharges. Chloride levels as high as 22,000 mg/l have been recorded from dry season samples from the C-10 canal. Increased salinity regimes may have a profound change on the ecology of these waters and on the surrounding natural areas, such as cypress remnant stands on the New River, Cypress Creek and Middle River. In further evaluation of alternative D13R4, the operational schedule should consider minimizing these potential impacts.

Design of West Miami-Dade Reuse Facility in D13R4: The reconfiguration of discharge from the West Dade Reuse facility is of concern. Under D13R, discharge from the facility was proposed to either to the Bird Drive Recharge Area or the South Dade Conveyance System (SDCS). Pumping to the Bird Drive Recharge Area could provide an additional margin of water quality polishing prior to recharging the Biscayne aquifer and subsequently the West Wellfield (located just south of the Bird Drive Recharge Area) or to meeting demands elsewhere. Alternative D13R4 propose to move this water directly to the SDCS without temporary storage in a marsh system.

D-E.3.10.9 Interpretation of Scores for LECSAs

Summary: Based on the above interpretation of the performance measures, Alternatives D13R and D13R4 perform equally well and substantially improve water supplies compared to the 2050 Base for the Lower East Coast Service Area. The component changes between Alternative D13R and D13R4 do not negatively effect the LECSAs as modeled with the SFWMM. The one exception is a slight increase in water supply cutbacks in Service Area 2. The additional two months of cutbacks is not significant in itself, but do cause concern and warrants further investigation during the next phase of study.

North Palm Beach Service Area: The North Palm Beach Service Area scores very well, almost reaching the established goals in all alternatives. The scores for alternatives D13R and D13R4 reach 99%. The performance of the primary canals reaches their goals in all of the alternatives. The 1-in-10 level of service planning goal scores are met. The duration of cutbacks scores are very high as well and are just shy of reaching their goal. Compared to the 2050 Base, either of the proposed alternatives relying on alternative sources would provide additional water supplies to meet projected water demands, reduce the frequency and duration of water supply cutbacks and help abate saltwater intrusion in the North Palm Beach Service Area.

Service Area 1: Service Area 1 performs very well almost reaching the established goals in alternatives D13R and D13R4. The Scores for Alternative D13R and D13R4 reach 99%. The performance of the primary canals reaches their goals in both of the alternatives despite keeping more water west of the control structures to meet other demands further south in the system. The 1-in-10 level of service planning goal scores very high in all alternatives, above 95%. The duration of cutbacks scores are very high as well and are just shy of reaching their goal. Compared to the 2050 Base, either of the proposed alternatives relying on alternative sources would provide additional water supplies to meet projected water demands, reduce the frequency and duration of water supply cutbacks and help abate saltwater intrusion in Service Area 1.

Service Area 2: Service Area 2 performs well in alternatives D13R and D13R4. The average scores for these two alternatives are 93% for D13R4 and 96% for D13R. This compares very favorably to the 2050 Base, which scores only 54% for Service Area 2. The ability to maintain primary coastal canals performed well in both of the alternatives. It is just shy of reaching its goal despite keeping more water west of the control structures to meet other demands further south in the system. The 1-in-10 level of service planning goal score for all of the alternatives is significantly higher than the 2050 Base, which has cutbacks almost every year, scoring a dismal 4%. Although Alternative D13R4 scores slightly lower than D13R, the actual difference is two more months of cutbacks over the period of record in Alternative D13R4. This is reflected in the duration performance measure. The duration of cutbacks scores improve significantly when compared to the 2050 Base. Compared to the 2050 Base, either of the proposed alternatives would provide additional water supplies to meet projected water demands, reduce the frequency and duration of water supply cutbacks and help abate saltwater intrusion in Service Area 2.

Service Area 3: In Service Area 3, the overall performance improves in alternatives D13R and D13R4 compared to the 2050 Base. The score for these two alternatives is 92%. This compares favorably to the 2050 Base, which scores only 70% for Service Area 3. Both of the alternatives performed well in maintaining the primary coastal canals. The other canals in southern Miami-Dade County score well, but fail to perform well enough to reach their targets. Both of the alternatives' perform equally well to improve meeting the 1-in-10 level of service planning goal when compared to the 2050 Base. The duration of cutbacks scores very high for both alternatives, with Alternatives D13R and D13R4 performing equally well. Except for maintaining water levels in southern Miami-Dade canals, the performance of both of the alternatives as evaluated in the matrix exceeds the performance of the 2050 Base.

* Flood protection not evaluated in this matrix

D-E.3.11 Biscayne Bay

D-E.3.11.1 Biscayne Bay Flows

Flows to South and Central Biscayne Bay increased and exceeded targets, but dry season flows to Snake Creek were less than D13R and less than target, and dry season flows to the Miami River decreased relative to D13R.

****Snake Creek***: D13R4 flows are very slightly reduced relative to D13R in the wet season, but are reduced by 23% relative to D13R in the dry season. Flows under D13R4 exceed the target in the wet season but are only 22% of target for the dry season (28% of target for D13R).

North Bay: D13R4 flows are approximately equal to 2050 Base and D13R flows in both wet and dry seasons, and are slightly smaller than 1995 Base flows.

****Miami River***: D13R4 flows are 14% higher in the wet season but 1% lower in the dry season than D13R. Since no targets were specifically set for the Miami River, flow volumes to this region should be considered interim until such time as a thorough evaluation is conducted of hydrodynamic and water quality issues in this portion of Biscayne Bay.

Central Bay: D13R4 flows are higher than the target, D13R, 1995 Base and 2050 Base. Both wet season and dry season targets would be met without any input of South Miami Dade coastal reuse water.

South Bay: D13R4 flows are higher than the target, D13R, 1995 Base and 2050 Base. The dry season target would be met without any input of South Miami Dade coastal reuse water.

Card and Barnes Sounds and Manatee Bay: While no specific performance measures were prepared concerning flows to southernmost Biscayne Bay, this area is expected to be seriously deficient in freshwater inflow relative to needs, once current C111 plans are implemented, and the objective is to replace canal discharge with overland flow through adjacent coastal wetlands. Expected improvements in overland flow can be estimated based on water levels in the wetlands (i.e., the Model Lands). While D13R4 provides slightly higher water levels in the coastal wetlands, compared to D13R, this is not likely to be enough to overcome the serious deficiency in consistent freshwater flow to that part of the bay.

Target and Model-Estimated Mean Annual Surface Flows to Biscayne Bay (in thousands of acre feet/year) under the 1995 base condition and Alternatives D13R and D13R4 (values for Central Bay and South Bay are calculated without coastal reuse water inputs).

Table 12. Surface Water Flows to Biscayne Bay

	Wet season	Dry season

Region	Target	95Base	D13R	D13R4	Target	95Base	D13R	D13R4

D-E.3.13 Big Cypress

D-E.3.13.1 AREA/SUBREGION/INDICATOR REGIONS

Different portions of the Big Cypress subregion are used in the different matrix equations.

D-E.3.13.2 PERFORMANCE MEASURES

1. Mean NSM Hydroperiod Matches for North Big Cypress National Preserve for the 31 year simulation

2. Mean NSM Hydroperiod Matches for South Big Cypress National Preserve for the 31 year simulation

3. Normalized Weekly Stage Duration Curves for Indicator Regions 13, 31, 36-40, 45, and 42-43

4. Average Annual Overland Flows toward Gulf of Mexico from Big Cypress National Preserve for the 31 year simulation

5. Inundation Duration Summary for Indicator Regions: Average Flood Duration

D-E.3.13.3 Scoring Explanation

All of the scores are relative to NSM conditions in the Big Cypress.

A = percent of North Big Cypress National Preserve that matches NSM (PM #1). This provides a spatial measure of one of the more impacted portions of the Big Cypress that lies along its northern border. Impacts are due primarily to agricultural development and its associated canals upstream (north) of this area. In addition, there may be some model boundary problems in this area, possibly related to the fact that the area to the north is included in the Natural System Model, but not the South Florida Water Management Model.

B = percent of South Big Cypress National Preserve that matches NSM (PM #2). This provides a spatial measure of the relatively unimpacted portion of the Big Cypress. This area is dominated by rainfall inputs, and as a result, exhibits few effects of hydrologic alterations beyond its boundaries. Hydrologic effects of the Restudy alternatives occur primarily along the Big Cypress boundary with the Everglades.

C (for individual Indicator Regions) = 1 - {absolute number [(percent of time flooded for NSM) - (percent of time flooded for Base or Alternative)] /100} (PM #3). This provides a measure of deviation from NSM hydroperiod for an

Indicator Region. This deviation is almost always a reduction in hydroperiod. The selected Indicator Regions are all in the eastern portion of the Big Cypress near its border with the Everglades, since there is little effect of any of the Alternatives on the western portion of the Big Cypress. Initially all of the Indicator Regions were evaluated separately (Table 14).

Equations were developed to combine some Indicator Regions in a simple additive form because of different influences in different areas. Indicator Regions 31, 36-40, and 45 were combined since they are all probably influenced by flows in the vicinity of South L-28 (South Big Cypress). Indicator Regions 42 and 43 were combined since they are both in the area affected by the L-28 Interceptor and the Western Feeder Canal (North Big Cypress). Indicator Region 13 was not combined with any other Indicator Regions (Southeast Big Cypress).

D_n(for individual Indicator Regions) = 1 – absolute number [(maximum deviation from NSM hydrograph) / (maximum range of NSM water level fluctuation)] (PM #3). This provides a measure how much water levels have been altered from NSM conditions as a function of the NSM range of fluctuation for an Indicator Region. A certain degree of deviation in an area with a large natural fluctuation would be less significant than in an area with a small natural fluctuation. Typically, the greatest deviation occurs when the water table is declining through the first foot or two below the ground surface, it is smallest at its lowest point on the hydrograph, and it is relatively small when the water table is above ground. The selected Indicator Regions are all in the eastern portion of the Big Cypress near its border with the Everglades, since there is little effect of any of the Alternatives on the western portion of the Big Cypress. Initially all of the Indicator Regions were evaluated separately (Table 14).

Equations were developed to combine some Indicator Regions in a simple additive form because of different influences in different areas (Table 14). Indicator Regions 31, 36-40, and 45 were combined since they are all probably influenced by flows in the vicinity of South L-28 (South Big Cypress). Indicator Regions 42 and 43 were combined since they are both in the area affected by the L-28 Interceptor and the Western Feeder Canal (North Big Cypress). Indicator Region 13 was not combined with any other Indicator Regions (Southeast Big Cypress).

G = 1 – absolute number [(deviation of average flood duration from NSM average flood duration) / (NSM average flood duration)] (PM #5). This provides a measure of deviation from NSM for average duration of individual flooding events for an Indicator Region. This deviation is usually a reduction in the duration of inundation. The selected Indicator Regions are all in the eastern portion of the Big Cypress near its border with the Everglades, since there is little effect of any of the Alternatives on the western portion of the Big Cypress. Initially all of the Indicator Regions were evaluated separately (Table 14).

Equations were developed to combine some Indicator Regions in a simple additive form because of different influences in different areas (Table 14). Indicator Regions 31, 36-40, and 45 were combined since they are all probably influenced by flows in the vicinity of South L-28 (South Big Cypress). Indicator Regions 42 and 43 were combined since they are both in the area affected by the L-28 Interceptor and the Western Feeder Canal (North Big Cypress). Indicator Region 13 was not combined with any other Indicator Regions (Southeast Big Cypress).

E_w = 1 – absolute number [(deviation of wet season flows from NSM flows) / (NSM wet season flows)] (PM #4)

E_d = 1 – absolute number [(deviation of dry season flows from NSM flows) / (NSM dry season flows)] (PM #4)

Total flows during the wet and dry season provide another way of expressing hydrologic conditions and how they change in response to proposed Alternatives in particular portions of the Big Cypress. The flow cross-sections evaluated included the Eastern Big Cypress and Lostman's. Initially the flow cross-sections were evaluated separately by wet and dry season (Table 14).

I have developed simple additive equations for each flow cross-section to combine the wet and dry season information (Table 14).

D-E.3.13.4 Summary Equations

I subsequently developed summary equations for major geographic regions of the Big Cypress that were distinct in terms of their response to the various Restudy alternatives (Table 14). These major areas were: North Big Cypress, which was only affected by Alternatives C and D where the L-28 Interceptor canal and levee system were modified; South Big Cypress, which was affected primarily by alterations to the south end of the L-28 canal and levee and in the adjacent Water Conservation Area 3A; and Southeast Big Cypress, which being on the border between the Everglades and southeast portion of the Big Cypress Swamp, is affected by the numerous alterations to the Everglades.

For each of these geographic areas, a simple additive equation was developed to combine variables C_n, D_n and G_n for the same Indicator Region(s) to summarize information on deviations in hydroperiod, water depth, and average flood event duration in these areas. In North Big Cypress, I included variable A in this simple additive equation. In South Big Cypress, I included variable B and variable E for flows across the Eastern Big Cypress along Tamiami Trail. In Southeast Big Cypress, I included variable E for flows across the Lostman's cross-section south of Tamiami Trail.

I also developed a single equation that combined the three Big Cypress regions.

D-E.3.13.5 Discussion

Scores were developed separately for each variable in each Indicator Region and for each cross-section or boundary (Table 14). I then combined them in a stepwise fashion, as described above, so that the AET would be able to comment on what is gained and lost as each Performance Measure was combined with others. Originally I developed two sets (with or without flows) of the three summarizing equations, with the goal of reducing all of the variables to three scores, one for the North Big Cypress, one for the South Big Cypress, and one for the southeastern Big Cypress. I ultimately produced two whole Big Cypress equations, again depending on whether flow parameters are used or not in the equations.

As a result of discussions at the late May AET meetings, I decided to focus on using the information contained in the three geographically separate equations that included the flow cross-section information (Table 14). Each of these three summary rows of the matrix provided distinctive information relevant to understanding influences that each of the Alternatives had on the Big Cypress.

All of the effects on the North Big Cypress occurred in Alternatives C and D, and were retained in D13, D13R, and D13R4. The effects resulted from filling the L-28 Interceptor Canal and removing its western levee, creating openings for water to move south along the Western Feeder Canal, and replacing S-190 with a pump station to maintain upstream drainage. This scenario also required some sort of water treatment capability to assure that all water moving south and southwest from the upstream canal system would provide only clean water. These components converted an area about two cells wide for most of the length of the L-28 Interceptor along its western side to approximately NSM conditions. Because the locations of the restored cells and the Indicator Regions available in the vicinity were not the same, the low matrix scores did not adequately reflect the high degree of restoration that actually occurred in portions of this area from the implementation of these components.

In the South Big Cypress, the most significant changes occurred in Alternative D, with the removal of the L-28 Tieback Levee. With this structure removed, hydrologic conditions showed almost complete restoration to NSM conditions, including restored hydroperiods and increased flows across the eastern portion of the Big Cypress. The model results for D13, D13R, and D13R4 were almost identical to one another, and (delete "both") showed generally small but distinct increased deviations from NSM (drier than NSM) as compared to Alternative D. The matrix values for D13 were almost identical to the 95 Base conditions in this area, but were higher (wetter) than for the 2050 Base. When looking at the hydrologic responses to these alternatives for individual Performance Measures and Indicator Regions, the geographic area where the deviations were greatest was in the vicinity and downstream of the jetport. We determined that the jetport was not modeled in the SFWMM, so it is not the cause of the problem. The somewhat poorer conditions in South Big Cypress relative to NSM in the D13 scenarios seemed to be associated with the movement of water to the east rather the west as occurred under NSM conditions in the vicinity of the Jetport. This change in flow direction appeared to result from a slightly lower-than-NSM topography that currently exists in this area in the SFWMM. It did not occur prior to Alternative D13 because of the presence of L-28.

In the southeastern Big Cypress along its border with the Everglades and below Tamiami Trail, the most significant changes occurred in Alternative B, when the L-28 and L-29 levees and canals were removed. According to the model, there were larger areas showing reduced hydroperiods and the reductions in hydroperiods and flows were greater than in Alternatives A, C, or D, all of which were close to NSM condition. In Alternative C, the L-28 and only the western portion of L-29 were restored, which was sufficient to return conditions in this area close to NSM. The removal of the L-28 Tieback in Alternative D did not seem to affect this portion of the Big Cypress. Alternatives D13, D13R, and D13R4 produced generally small and variable responses among the various Performance Measures, resulting in an overall minor difference in the summary matrix value for this portion of the Big Cypress.

D-E.3.13.6 Summary

The combination of components in Alternative D produced the greatest benefits in terms of restoring the largest amount of area in the Big Cypress to approximately NSM conditions. It also seems that several of the most beneficial components could be implemented in any of the Alternatives, since they operate pretty much independently from the rest of the Everglades ecosystem. This would be the situation for the L-28 Interceptor and L-28 Tieback components. Changes to the L-28 South and L-29 have more extensive and complex interactions with other parts of the Everglades.

In using the colors and grades to differentiate restoration success as indicated by the various Performance Measures for each the Bases and Alternatives (A-D, D13, D13R, D13R4), I used matrix value ranges of 86-100 (green, grade A), 71-85 (yellow, grade B), and <71 (red, grade C). These ranges generally seemed to do a reasonably good job of sorting restoration gains and losses for the Big Cypress region that were associated with each of the Alternatives. The only portion of the region where these results could be misinterpreted is the North Big Cypress. The portion of this area influenced by the L-28 Interceptor system should be included in the green grade A category in Alternatives C, D, D13, D13R, and D13R4. The portion further west still shows severe hydrologic impacts, even in these latter Alternatives. However, based on a helicopter overflight of the area to assess its condition and our understanding of how the models are operating in this area, it is very likely that these impacts are merely the result of modeling problems, and in reality are much less severe than suggested by the SFWMM.

There were no significant changes in the Big Cypress performance measures from alternative D13R. North Big Cypress has not changed since Alternative C when the L-28 Interceptor canal and its west levee were removed and water from the upstream North and West Feeder canals was distributed as sheet flow across the northeastern Big Cypress. Southeast Big Cypress has maintained fairly constant conditions since Alternative A, with the exception of Alternative B, which produced the most adverse effects of Alternatives A-D and the D13s. Hydrologic conditions in the South Big Cypress were closest to NSM under Alternative D and were close to 1995 Base conditions and slightly better than the 2050 Base in the D13R scenarios. The somewhat poorer conditions in South Big Cypress relative to NSM in the D13 scenarios seemed to be associated with the movement of water to the east rather than the west as occurred under NSM conditions in the vicinity of the Jetport. This change in flow direction appeared to result from a slightly lower-than-NSM topography that currently exists in this area in the SFWMM. It did not occur prior to Alternative D13 because of the presence of L-28.

D-E.3.14 ATLSS / Threatened and Endangered / Keystone Species

D-E.3.14.1 Cape Sable seaside sparrow

For the western subpopulation, inspection of performance measure graphics for indicator region 46 might suggest a negligible difference in effects to sparrows for the D13R4 and D13R alternatives. However, ATLSS individual-based modeling for this subpopulation is relatively sensitive to what appear to be minor shifts in the stage duration curves. A small change in the timing and duration of flooding can have a pronounced effect on population projections in the ATLSS model. ATLSS modeling results for D13R4 are similar to D13R, but show a greater tendency for subpopulation numbers to drop below 500 individuals. In addition, D13R4 results are only a slight improvement over 2050 Base conditions according to the ATLSS results. The Service believes that these results indicate that there is potential for significant adverse effects to the western subpopulation of the Cape Sable seaside sparrow within the range of flexibility demonstrated for alternative D13R. As a result, any Restudy implementation effort that proceeds toward the "wetter" range of possible D13R scenarios must exercise extreme caution with regards to possible effects on the sparrow's western subpopulation. ATLSS individual modeling for these subpopulations provides a far more detailed and sophisticated analysis of expected effects on sparrow demographics than do the indicator region graphics. Therefore, the U.S. Fish and Wildlife Service believes that the ATLSS modeling provides the best currently available scientific information for assessing effects to the endangered Cape Sable seaside sparrow.

For the eastern subpopulations C, E and F, D13R4 hydroperiods are significantly increased as compared to D13R and are slightly longer than NSM. While it is difficult to predict what effects these longer-than-NSM hydroperiods might have on the eastern marl prairie habitats, adverse effects to sparrow habitat have been documented as a result of increased hydroperiods resulting from S332 pumping in subpopulation C. Careful monitoring will be necessary if/when such a scenario is implemented. Overall, D13R4 should provide improved habitat conditions for the sparrow as compared to 2050 Base.

D-E.3.14.2 Wood stork

Based on John Ogden's revised stork performance measure (Table 15), alternative D13R4 provides significantly improved conditions for nesting in the historically important Shark Slough and Taylor Slough mangrove fringe as compared to D13R and both base cases.

D-E.3.14.3 Crocodile and Manatee

Based on the Shark and Taylor Slough flow lines, and P-33 salinity predictions for Florida Bay, D13R4 should provide increased habitat suitability for crocodiles and manatees as compared to D13R and both base cases.

D-E.3.14.4 Snail kite

ATLSS snail kite foraging index results show that foraging condition values for both D13R4 and 2050 Base are high across large parts of the remaining Everglades under very wet conditions. However, under D13R4, water levels are too high in parts of each of the WCAs to provide effective snail kite foraging. In addition, losses of snail kite nesting substrate in these areas, particularly in WCA-3B, would be expected during high water conditions produced by D13R4. Under very dry conditions, D13R4 provides slightly higher foraging condition values than 2050 Base in WCA-1, WCA-3B and the periphery of Shark Slough. Overall, D13R4 results are similar to those for D13R, except for reduced foraging and nesting habitat under very wet D13R4 conditions.

Table 15
Summary of wood stork performance measure elements

Performance Element	NSM	95 Base	2050 Base	D13R	D13R4
IR 9 innundation duration	176	75	98	156	174
IR 10 innundation duration	321	93	108	398	265
IR 9 ratio to NSM	1.0	0.43	0.56	0.89	0.99

APPENDIX E
SOCIO – ECONOMICS

E.1 INTRODUCTION

E.1.1 BACKGROUND

The Central and Southern Florida (C&SF) Project, authorized in 1948, is a regional system of levees, canals, water control structures, and management operations that were designed to provide flood control, water supply, and other services to southern Florida. Although the project has performed its intended purposes well, it has also contributed to the decline of the south Florida ecosystem, including the Everglades. In response to this decline, Congress authorized the U.S. Army Corps of Engineers (Corps) to conduct the C&SF Project Comprehensive Review Study (Restudy) to develop a comprehensive plan for the purpose of restoring, preserving, and protecting the south Florida ecosystem. The Restudy is being conducted in cooperation with the South Florida Water Management District (SFWMD), the non-Federal sponsor.

The Congressional authorization for the Restudy (Water Resources Development Act of 1996) specifies that the comprehensive plan include features necessary to provide: (1) for the protection of water quality in, and the reduction of the loss of fresh water from, the Everglades and (2) for the water-related needs of the region, including flood control, water supply, and other objectives of the C&SF project. The C&SF Restudy reconnaissance report was completed in November 1994. The feasibility phase of the Restudy was initiated in August 1995. In the authorizing legislation, Congress directed that the feasibility study – and the Environmental Impact Statement – be completed by 1 July 1999.

E.1.2 PURPOSE OF THIS INVESTIGATION

This investigation assesses the economic effects of the five alternative ecosystem restoration plans formulated in the feasibility phase of the Restudy. The economic evaluation of the alternative restoration plans includes five principal elements:

1. <u>Socio-economic Profile of the Study Area</u>: This profile includes population and economic forecasts for the region, as well as projections of future water demand.

2. <u>Anticipated Effects of Alternative Plans on the National Economic Development (NED) Account</u>: Alternative plans could result in positive or negative effects on net national economic efficiency due to project-induced impacts on the following economic activities in south Florida:

- Agricultural water supply,
- Municipal and industrial (M&I) water supply,
- Flooding potential,
- Commercial navigation,
- Recreation (Everglades-related), and
- Commercial and recreational fishing.

3. Evaluation of Project Costs: Project costs include all expenditures required to implement the alternative plans. These costs will be shared by the Federal government and the State of Florida. Project costs include those for initial construction; lands; relocations; rights of way; rehabilitation, replacement, and repair; and operations and maintenance (O&M) (including the costs of post-construction monitoring and adaptive management).

4. Regional Economic Development (RED) Effects: The potential RED effects of the alternative plans include changes in income, employment, or economic output of the region.

5. Other Social Effects (OSE): The potential social effects of the alternative restoration plans include effects on minority, elderly, and disadvantaged groups, population displacement, and effects on community cohesion.

The economic analysis for the C&SF Restudy was conducted consistent with Federal statutes and Corps policy. Procedures for estimating NED and RED effects are specified in the Economic and Environmental Principles and Guidelines for Water and Related Land Resources Implementation Studies (U.S. Water Resources Council, 10 May 1983), Engineering Regulation (ER) 1105-2-100, and other Corps guidance.

E.1.3 STUDY AREA

The Restudy study area encompasses the 16-county jurisdictional area of the SFWMD. At the heart of the study area – and the C&SF Project – is Lake Okeechobee. This shallow lake encompasses approximately 730 square miles, making it the second largest freshwater lake within the contiguous United States. Lake Okeechobee is primarily fed by the Kissimmee River basin to the north. Water leaves the lake through three principal avenues. First, as a result of the warm south Florida climate, the lake loses tremendous amounts of water to evaporation. Second, when lake stages are excessively high, water is released eastward to the Atlantic Ocean via the St. Lucie canal, and also westward to the Gulf of Mexico via the Caloosahatchee River. Finally, lake water is released southward via a system of water supply structures and canals. Major water supply conduits include: the Miami, North New River, Hillsboro, and West Palm Beach canals. These canals convey water for: (1) agricultural uses in the Everglades Agricultural Area (EAA), (2) agricultural and M&I uses in the eastern portions of Palm Beach, Miami-Dade, and Broward counties (and by extension, Monroe County, whose water supply comes from Dade County wells), and (3) maintenance of water levels and flows in the Water Conservation Areas (located southeast of Lake Okeechobee) and the Everglades National Park (via the Water Conservation Areas).

The SFWMD has divided south Florida into a set of water supply planning areas. These planning areas are referenced frequently in this document. They include the Lake Okeechobee Service Area (LOSA) and the Lower East Coast (LEC) of south Florida. These areas include the five sub-areas of the LOSA and the three urbanized service areas of the LEC. The five LOSA sub-areas consist of: (1) northern Palm Beach County, (2) the Everglades Agricultural Area which primarily lies within western Palm Beach County but also eastern Hendry County, (3) the northern lake district, (4) the Caloosahatchee basin, and (5) the St. Lucie basin. LOSA also includes two Seminole Indian reservations, Brighton and Big Cypress. The three service areas (SA1-SA3) within the LEC primarily lie within Palm Beach, Broward, and Miami-Dade counties, respectively.

E.1.4 ALTERNATIVE RESTORATION PLANS

The five alternative restoration plans (A, B, C, D, and D13R) have been formulated in the feasibility phase of the Restudy. Each alternative consists of a suite of structural and operational changes to the C&SF Project. These modifications to the regional water management system are designed to change the hydrology of south Florida to achieve the Restudy objectives, primarily restoration of the structures and functions of the Everglades ecosystems.

E.1.5 METHODOLOGY

A number of factors were considered prior to developing the methodologies used to evaluate the economic effects of the alternative restoration plans. These factors include: available analytical tools, economic theory, Federal policy, obtainable data, and time and budgetary constraints. These factors are discussed below.

E.1.5.1 South Florida Water Management Model

The SFWMD's South Florida Water Management Model (SFWMM) is the primary analytical tool being used in the C&SF Restudy to evaluate and compare the hydrologic effects of the alternative plans. The SFWMM is a regional-scale, continuous simulation, hydrologic model that was developed by the SFWMD. The SFWMM simulates the hydrology and water management of southern Florida from Lake Okeechobee to Florida Bay. The SFWMM spans a region that includes most of Florida south of Lake Okeechobee. Of this region, 7,600 square miles are divided into a 2-mile by 2-mile model grid. The SFWMM simulates system-wide hydrologic responses to daily climatic parameters (rainfall and evapotranspiration) in each of these 4-square mile cells.

The entire LEC, as well as two LOSA sub-areas (the EAA and Northern Palm Beach County) are included in the model grid. While flows to and from some tributaries to Lake Okeechobee, such as the Kissimmee River, are included in the model, they are not contained within the 4 square-mile grid cells. Similarly, the Caloosahatchee and the St. Lucie basins – both part of the LOSA – are not included in the grid.

The SFWMM simulates infiltration, percolation, evapotranspiration, surface and groundwater flows, levee underseepage, canal-aquifer interaction, current or proposed water management structures, and current or proposed operation rules for those structures. The model does not allow for dynamic changes in south Florida's land use/land cover or for changes in the C&SF infrastructure during the simulation period. As a result, the simulations associated with existing and future with and without plan conditions represent water management in the C&SF system given static structural and operational parameters under 31 years of historic climatic conditions (1965-1995). The current version of the model generates over 11,000 sequential daily simulations to cover the 31-year simulation period.

E.1.5.2 Limitations of the SFWMM Model for Use in Economic Analyses

The SFWMM is an operational model whose primary purpose is to assist the SFWMD in optimizing water management and allocation decisions. The model was not designed to conduct economic analysis, but does include many indicators of hydrologic change which can have economic consequences. To assist in estimating the economic effects of water management decisions, the SFWMD developed the Economic Post-Processor (EPP) to estimate the economic effects of cutbacks in agricultural and urban water supply during drought periods. The EPP was used in the Restudy economic analysis to estimate the impacts of alternative restoration plans on the frequency and duration of drought-induced changes in agricultural and urban water supply. Other categories of economic effects were estimated by conducting "outside-the-model" analyses of various SFWMM-generated hydrologic performance indicators.

E.1.5.3 Without-Plan and With-Plan Conditions

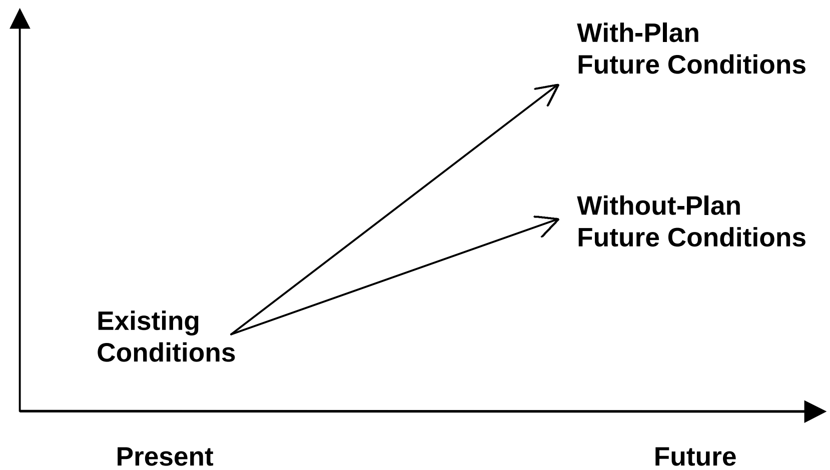
Using the SFWMM as the principal tool for evaluating the economic effects of alternative restoration plans requires some practical modifications to the traditional with and without-plan analysis procedures typically used in Corps of Engineers water resource planning studies. In a traditional feasibility investigation, a probabilistic analysis is conducted to project conditions expected to occur throughout the planning period (typically 50 years), both with and without implementation of a plan. "Average annual" economic impacts are estimated by evaluating a range of possible future conditions, weighting the likelihood (i.e., probability) of these conditions by their economic effects, and then statistically combining them. The difference between "average annual" with and without-plan conditions constitutes the net annual economic impacts (positive or negative) of the alternative plans.

This type of with and without-plan analysis had to be modified during the C&SF Restudy to account for the limitations imposed by SFWMM. As stated previously, the SFWMM is a simulation model which equally weighs each of the days in the 31-year simulation period. As a result, it is not possible to use SFWMM to determine the likelihood of occurrence of any given hydrologic event. While the 31 years of past climate data are considered representative of future climatic conditions, they are of insufficient duration to assign frequencies of occurrence to specific simulated hydrologic events (e.g., 25-, 50-, or 100-year return period events).

Therefore, the economic effects of the alternative restoration plans were estimated by comparing two "snapshots" of study area conditions that are expected to exist in the future, those with and those without restoration. As illustrated in ***Figure 1.5.3-1***, an alternative restoration plan (i.e., with-plan future conditions) will likely generate different economic effects – higher or lower – than those expected in the absence of restoration (i.e., without-plan future conditions). [This hypothetical figure is conceptual, and the with- and without-plan future conditions could be reversed, depending on the plan and the specific impact category.] For the Restudy, the SFWMM was used to generate two sets of simulations, 1995 and 2050, which were used as proxies for existing and future study area conditions Historical land use (1990) and historical water consumption data (1995) were used to estimate existing (1995) without-plan conditions. In the same way, projected future (2010) land use and projected (2050) water consumption were used to estimate the 2050 without-plan conditions. The model also simulates the changes in hydrologic conditions that are expected to occur with implementation of the alternative restoration plans (with-plan conditions) for 2050. Future without-plan and with-plan conditions were then compared to estimate the impacts of alternative restoration plans.

Depending on the alternative and the type of economic impact, changes resulting from implementation of a restoration plan may be desirable or undesirable when compared to the future without-plan condition. For example, alternatives which include modifications to the C&SF system to provide additional water storage areas may result in fewer economic losses associated with agricultural (irrigation) water shortages. This would be a desirable ancillary benefit of restoration.

FIGURE 1.5.3-1
COMPARISON OF WITH- AND WITHOUT-PLAN CONDITIONS



No attempt was made to project impacts for interim time periods or to discount effects back to present worth, because the rates of hydrologic change and habitat recovery in response to restoration efforts could not be determined. Only existing conditions and desired "end state" conditions could be accurately predicted by the SFWMM analysis. Since these are the causal factors which yield economic effects, it was also not possible to estimate economic consequences for interim years.

Two types of comparisons can be made to assist in the decision making process based on this type of with and without-plan analysis. First, existing (1995) conditions and future (2050) without-plan conditions can be compared to indicate how economic conditions might change over time in the absence of any restoration action. For example, future population growth in south Florida could be expected to place additional strains on the regional water supply system. Consequently, more frequent and more severe urban water shortages (relative to existing conditions) could be expected in the coming decades, in the absence of any Everglades restoration effort.

Second, without-plan future (2050) conditions and with-plan future (2050) conditions can be compared to determine what impact Everglades restoration activities are expected to have following implementation of a project. This is the typical comparison used to estimate the beneficial and negative effects of project implementation.

One type of comparison is not appropriate, however. Direct comparison of existing (1995) and future with-plan (2050) conditions is inappropriate, because it confuses the effects of plan induced changes with the longitudinal effects of future land use and demographic changes which will occur irrespective of a restoration project. Such a comparison would not allow decision makers to isolate the economic changes occurring in the study area regardless of whether restoration action is taken, or to determine the actual impacts of restoration actions.

E.1.5.4 Sources and Causes of Economic Effects

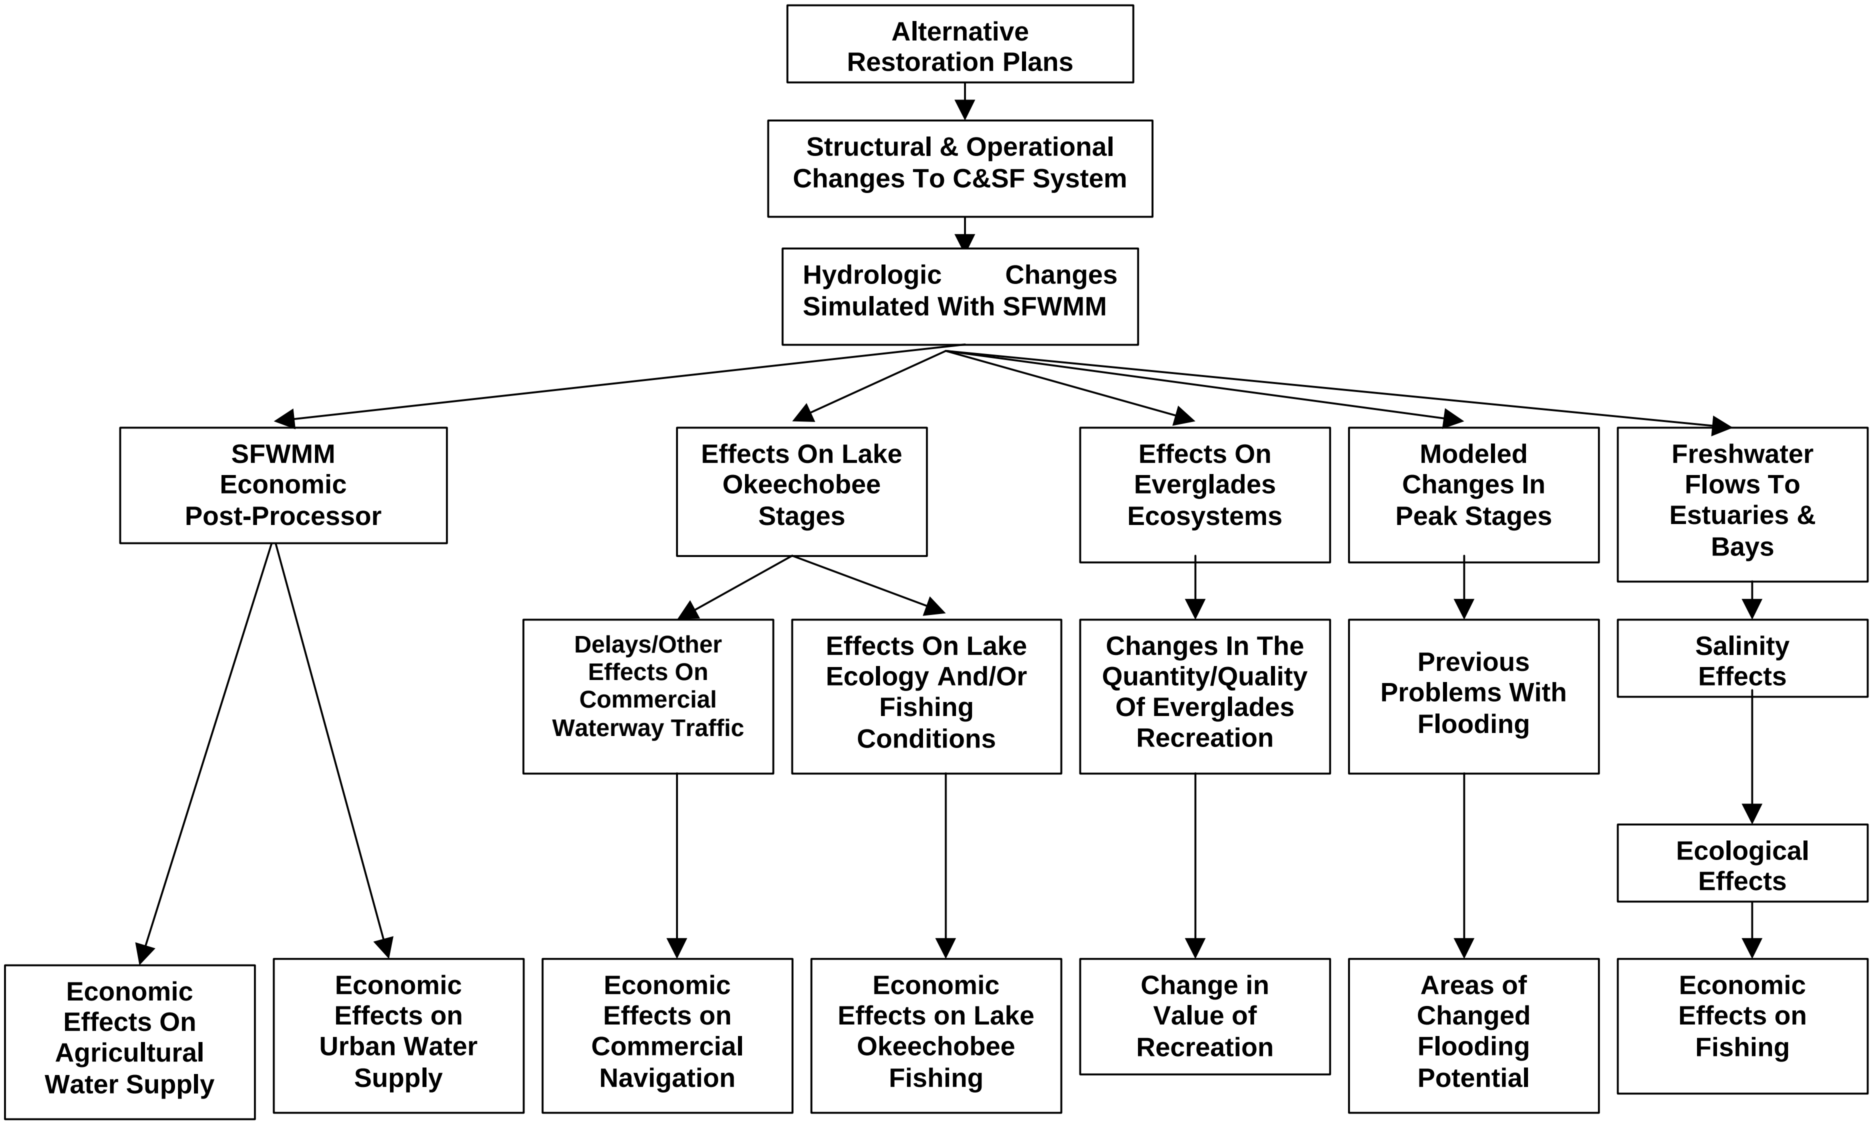
The potential economic impacts of the alternative restoration plans are a secondary consequence of the hydrologic changes which are expected to result from the proposed structural and operational modifications to the C&SF system. Figure 1.5.4-1 traces the causal linkages between the structural and operational modifications to the C&SF system and the different categories of economic effects.

Some categories of economic impact, such as urban and agricultural water supply effects, can be estimated directly from SFWMM-simulated hydrologic changes associated with each alternative restoration plan. Other economic effects, such as commercial and recreational fishing impacts in the St. Lucie and Caloosahatchee estuaries and in Biscayne and Florida bays, are less directly linked to the hydrologic changes resulting from the alternative restoration plans. In this latter case, the chain of cause and effect includes: the impacts of project-induced changes in water release rates, the impacts of changes in release rates on the productivity of the fisheries, and the impacts of changes in the fisheries on the net income of commercial fishing operations and the quality of recreational fishing experiences. As will become evident throughout this analysis, the difficulties in estimating these chains of cause and effect have important consequences for our ability to quantify the economic effects of the alternative plans. Economic analyses cannot be applied to estimate the value of physical or ecological impacts of the alternative plans if those impacts cannot first be defined and quantified.

E.1.5.5 Methodology for Conducting Economic Analysis

Since a traditional cost-benefit analysis was not conducted for the Restudy, the alternative restoration plans were compared using information in monetary and non-monetary units (***Figure 1.5.5-1***). The economic analysis of the Restudy's alternative restoration plans include: (1) the NED costs (in monetary terms), (2) the anticipated environmental benefits resulting from restoration measures (in non-monetary terms), (3) the positive and adverse NED effects expected to occur in the following economic impact categories: agricultural water supply, municipal and industrial water supply, commercial navigation, recreation, and commercial fishing (in monetary and non-monetary terms) and (4) the positive and adverse regional economic effects (RED) resulting from project implementation. This section of the report addresses items (1), (3) and (4) above.

FIGURE 1.5.4-1
SOURCES OF ECONOMIC EFFECTS



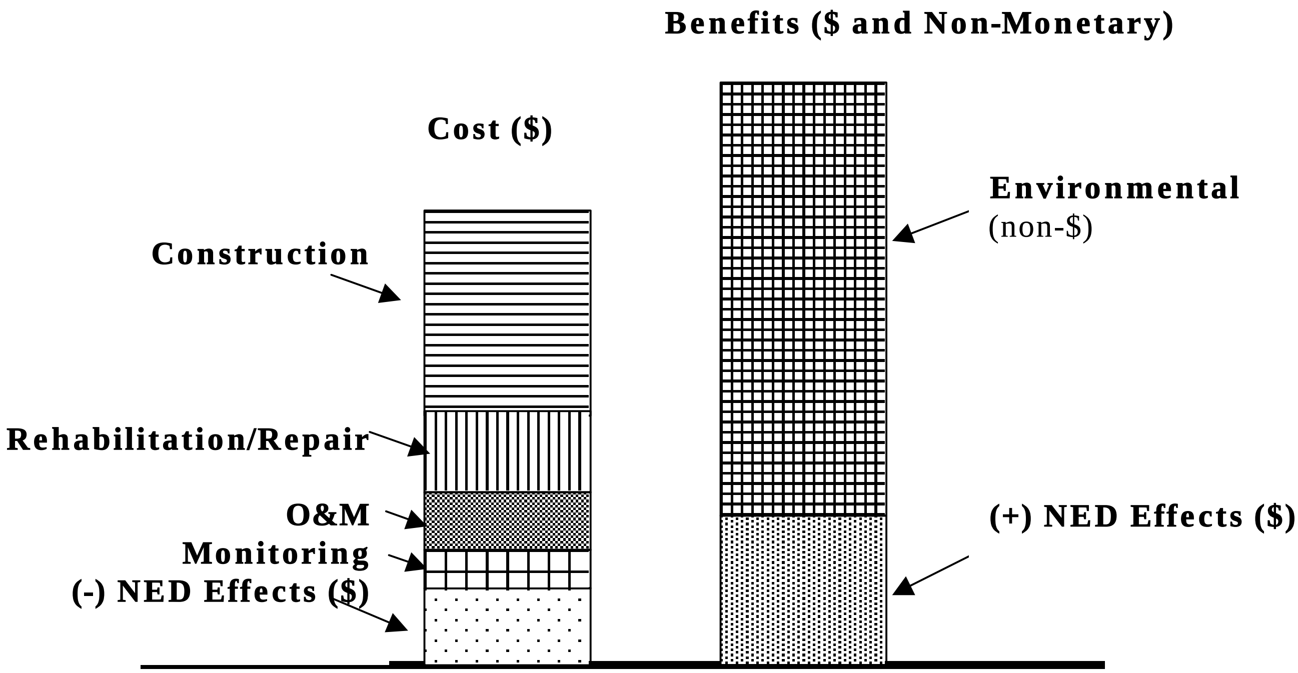


FIGURE 1.5.5-1
CONCEPTUAL COMPARISON OF RESTORATION COSTS AND BENEFITS

The methodologies used to conduct economic analysis studies for the C&SF Restudy were determined based on a combination of factors, including: economic theory, Corps of Engineers' ecosystem restoration and economic evaluation policies, and the characteristics of methodologies used by economists to value ecosystem benefits. The most important consequence of this determination is that traditional cost-benefit analysis procedures were not used to evaluate the primary output of the alternative restoration plans, i.e., improvements in environmental quality. Instead, cost effectiveness evaluation procedures were used to compare the costs and non-monetary ecosystem benefits of the proposed restoration efforts. The reasons for this decision are summarized below.

Theoretically, the economic basis for making policy decisions about whether to invest public funds in ecosystem restoration in South Florida is the same as for any other government spending program. The monetary and non-monetary costs and benefits of any proposed government project should be compared in order to determine whether the expenditure is justified and to select the plan which maximizes the net benefits to society for the investment of public funds. A conceptual comparison of costs and benefits of ecosystem restoration is illustrated in Figure 1.5.5-1. [In order to simplify the illustration, the full range of potential costs and benefits are not included in this figure; and, relative sizes of costs and benefits are conceptual.]

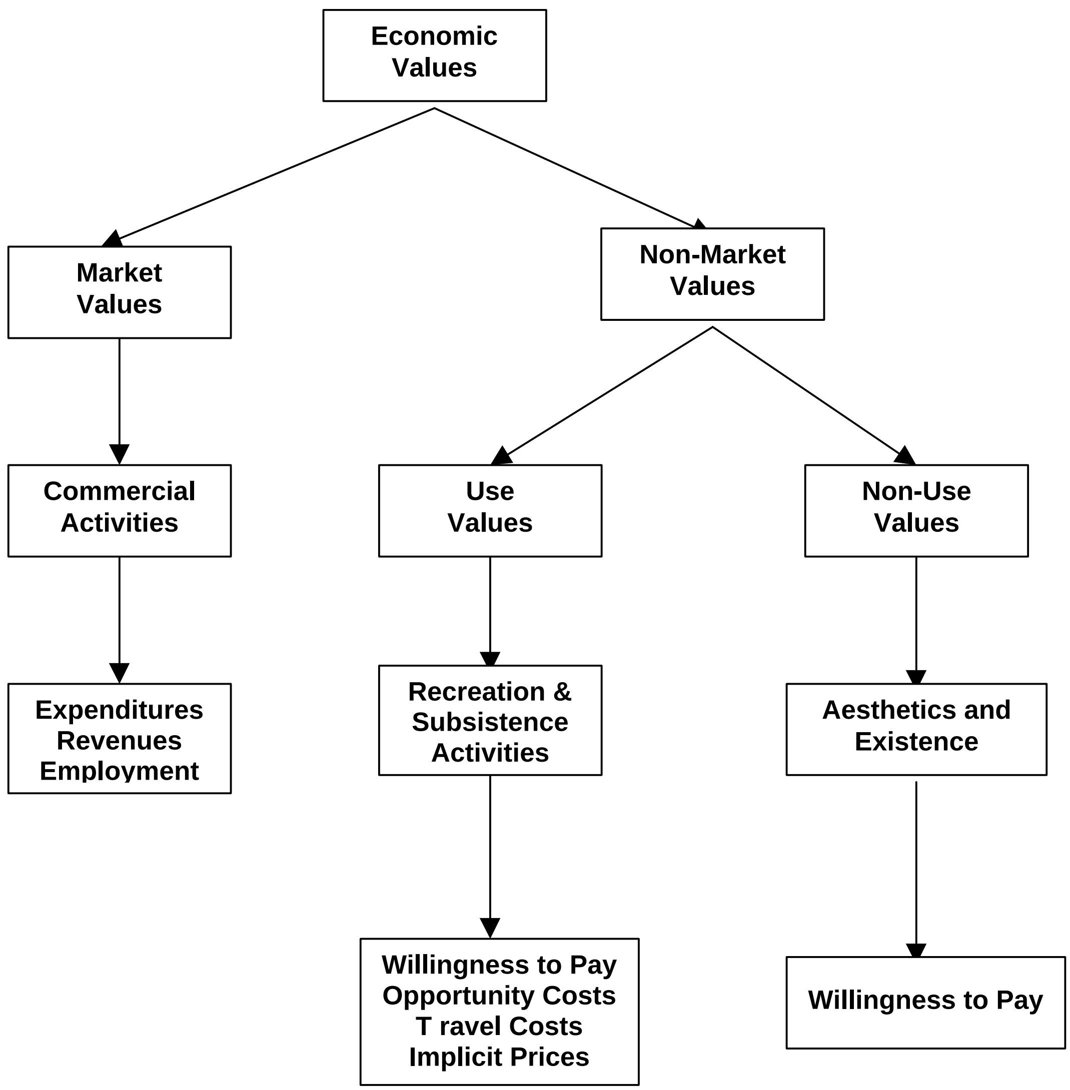
The costs of ecosystem restoration projects include: initial construction costs; major rehabilitation and repair costs; operations and maintenance (O&M) costs; post-construction monitoring costs; and adverse NED effects. Typically, these costs can be expressed in monetary (i.e., dollar) terms.

The principal challenge of ecosystem restoration economics is estimating the value of restoration benefits. As illustrated in Figure 1.5.5-1, the primary purpose (and therefore the primary benefits) of each alternative plan is ecosystem restoration. The benefits of ecosystem restoration are usually expressed by ecologists in non-monetary units, such as acres of specific habitat created or enhanced, indices of biological productivity associated with habitat improvement, or increased abundance and/or diversity of particular species of plants or animals. For decision making purposes, it would be desirable to express ecosystem restoration benefits in monetary terms, in order to compare them with project costs. Expressing the costs and benefits of alternatives in a common, monetary metric would facilitate selection of the best restoration plan for a given site. However, calculating the monetary value of environmental amenities is both difficult and controversial. Environmental amenities are public goods that are generally not exchanged in the marketplace. For marketable commodities (i.e., items that people buy and sell), the demand, and prices paid, for these goods can be used as “proxies” for determining their value to consumers. In the absence of data on consumers’ expenditures for environmental amenities, resource economists have attempted to develop techniques that can be used to estimate their value using indirect indicators of consumers’ “willingness to pay” for ecosystem restoration.

Figure 1.5.5-2 portrays a schematic of the different approaches used by economists to measure the economic value of both market and non-market goods. Market goods are produced by commercial activities. The value of these goods can be estimated based on the expenditures made to produce them, the prices paid by the purchaser, the income they generate for the producer, and the employment generated by producing them.

Ecosystems provide a myriad of goods and services to society. As explored by Costanza et al. (1997), these goods and services include climate regulation, water regulation, soil formation, waste treatment, food production, genetic resources, and recreation. Costanza et al. (1997) estimated that on a global scale the average annual value of ecosystem goods and services is in the range of $33 trillion. Many of the goods and services provided by ecosystems at the global scale are also provided by the Everglades ecosystems to south Florida and the nation.

FIGURE 1.5.5-2
DIFFERENT APPROACHES USED TO EVALUATE THE ECONOMIC VALUE OF BOTH MARKET AND NON-MARKET GOODS



For goods and services that are not purchased in the marketplace, non-market valuation approaches must be used to infer their value to the public. There are direct and indirect use values for these goods and services. Use values refer to the value consumers obtain from using a good that is related to an environmental amenity. For example, recreational fishermen in Florida Bay obtain direct use value from the Florida Bay fishery. The fishermen also obtain indirect use values from the Everglades ecosystem, since it provides ecological functions which contribute to the productivity of the Florida Bay fishery. Use values can be either consumptive or non-consumptive. Consumptive use values refers to the cases for which the good is consumed by the user and is no longer available to others, such as waterfowl hunting. Non-consumptive use values refer to the value obtained by a user in cases for which the good remains to be used by others in the future, such as catch-and-release fishing or bird-watching.

It is reasonable to expect that the alternative restoration plans will generate additional use values to the public. Non-market activities which would benefit from restoration plans include: recreational fishing, subsistence activities, and a whole variety of ecotourism related activities (e.g., bird-watching, hiking, canoeing, etc.).

Non-use values include the values the public obtains from simply knowing that the good or resource is available, even if they have not used it previously. Individuals may value a good simply from knowing it exists (existence value) or because the may want to have the opportunity to use it at some future time (option value).

Again, it is reasonable to expect that the alternative restoration plans will generate additional non-use values to the public. The tremendous interest in and support for Everglades restoration, not just in south Florida but throughout the country (and the world), is an indication that a broad segment of society values the Everglades ecosystem, even though most have never experienced the area first hand.

Theoretically, it should be possible to determine the value of restoring the Everglades ecosystem by asking people what they would be willing to pay for different levels and types of restoration projects, or by observing what they spend on ancillary costs (e.g., travel, subsistence, equipment, etc.) when they engage in these non-market experiences. Economists have developed a variety of techniques to estimate society's willingness to pay for these types of non-marketable environmental amenities. These economic valuation techniques include market-based, surrogate market, and non-market methodologies (see Freeman, 1993).

Market-based approaches estimate the value of environmental resources using information generated in the marketplace. These approaches include: changes in factors of production, valuation of complimentary goods and services, defensive expenditures, and market valuation of the next best alternative. Surrogate-market techniques estimate value on the basis of preferences revealed in surrogate markets. These techniques include: the travel cost method and hedonic valuation. The contingent valuation method (CVM) is the most widely accepted non-market valuation methodology. CVM is perceived as the most effective technique to determine society's willingness to pay for environmental protection and/or restoration and is the only technique able to estimate non-use (i.e., option and existence) values. This method is based on carefully designed surveys which solicit respondent's willingness to pay for a specific environmental resource in a given condition. The survey is intended to reveal both users' and non-users' willingness to pay for the resource.

Unfortunately, these surrogate-market techniques, including CVM, have significant shortcomings which lead to concerns about their reliability and validity. They are especially problematic in cases for which respondents are unfamiliar with the environmental amenity, when the issue is controversial, or where it generates strong reactions, based on ethical, rather than economic motivations. Most importantly for the Restudy effort, the reliability and validity of these techniques are especially questionable in situations in which the actual changes that would result from the restoration efforts are difficult to precisely describe or visualize. Finally, stated preference methods, such as CVM, can be expensive to implement, especially when multiple alternatives are being evaluated.

Therefore, Corps of Engineers ecosystem restoration policy has been formulated in recognition of the practical limits of available economic tools to value environmental resources. As specified in Corps of Engineers ecosystem restoration policy (EC 1105-2-210: Ecosystem Restoration in the Civil Works Program), ecosystem restoration projects are not subject to traditional benefit-cost analyses. Economic justification of ecosystem restoration is not required in the traditional sense of ensuring that the monetary benefits of the alternative plans exceed their monetary costs. An ecosystem restoration proposal must still be justified by comparing the monetary and non-monetary costs and benefits of restoring degraded ecosystems. However, Corps ecosystem restoration evaluation procedures focus on the non-monetary benefits of restoration, comparing these benefits to monetary costs through the use of cost effectiveness and incremental cost analysis procedures.

Costanza et al. (1997) argue that despite the uncertainties surrounding ecosystem valuation, the decisions that society makes about ecosystems imply valuations. One clear expression of the value of the Everglades ecosystem was made by the U.S. Congress in the authorization for the reconnaissance and feasibility studies of the Restudy and by the Administration in its strong support for the restoration effort. The explicit authorizing language and funding appropriations are tangible expressions of the value of the Everglades ecosystem to our society, as expressed through public policy decisions.

E.1.6 PRIOR STUDIES

The regional scale of this investigation, the diversity of potential economic effects of the alternative restoration plans, and the Restudy's accelerated schedule dictated the use of prior studies – and other secondary information – to the extent possible. These studies are contained in the reference list presented at the end of thisAppendix. However, the prior studies of two institutions deserve particular recognition. First, the Natural Resources Conservation Service (NRCS) was previously engaged in an interagency agreement with the Corps to perform agricultural water supply impact analyses. NRCS personnel were instrumental in developing a baseline of information regarding the relationships between crop yields and water stress. Personnel involved in the interagency cooperation were consulted as part of this study, and they provided valuable information and insight. Second, the SFWMD has previously conducted a wide variety of studies that directly or indirectly support this investigation. Interviews with SFWMD staff and review of SFWMD reports have contributed greatly to this investigation.

E.1.7 ORGANIZATION OF REPORT

The chapters which follow evaluate the economics of the five alternative restoration plans. Chapter 2 develops a socio-economic profile for the region, and Chapter 3 contains the water demand forecasts for the region. These chapters develop the basis for critical physical and economic effects of the with and without-plan future conditions. These effects were incorporated into the SFWMM runs and were instrumental in the assessment of potential NED effects of the alternative restoration plans in subsequent chapters, including agricultural water supply (Chapter 4), M&I water supply (Chapter 5), flooding (Chapter 6), commercial navigation (Chapter 7), recreation (Chapter 8), and commercial and recreational fishing (Chapter 9). The costs of the alternative plans are presented in Chapter 10. The regional economic effects and other social effects of the alternative plans are explored in Chapters 11 and 12, respectively. Finally, Chapter 13 presents a summary of the economic effects of the alternative plans and conclusions.

E.2 POPULATION AND ECONOMY

E.2.1 OVERVIEW

This section of the appendix includes a description of the economic and demographic aspects of the study area. This descriptive information provides insight into the study area's socio-economic characteristics, and provides part of the basis for different facets of the economic impact evaluation work in the rest of this appendix.

Population and employment projections are key input data for future M&I (municipal and industrial) estimated water use. Estimated future M&I water use is required input for using the SFWMM, the main analytical tool being used in this study. The socio-economic data are also important in the assessment of the "other social effects," discussed in Section 12 of this Appendix.

The people who live in the study area, and the economic activity in which they are engaged, comprise important components of the area's total environment. In addition to the direct use of this data for the water use projections and other social effects mentioned above, they represent the socio-economic environment for the other impact topics of flooding, water use shortages, fishing, recreation, and navigation.

Any course of action forthcoming from this study will have effects throughout an economic system as well as the natural ecosystem(s) whose health and sustenance is the impetus for, and a major focus of, this investigation. The economic system is connected with the natural ecosystem and in general is ultimately dependent upon it for survival. Changes in the economic system can cause change in the natural ecosystem and vice versa. It is significant, therefore, to describe and understand the general economic and social environment within which such changes could take place. The main focus of economic impact evaluation efforts has been to describe the impacts of alternatives being considered for implementation. Nevertheless, this broader description is also necessary and important.

E.2.2 STUDY AREA

The study area includes all of the area of the Central and Southern Florida (C&SF) Project with the exception of the Upper St. Johns River Basin. The study area stretches from Orlando to the southern tip of Florida and encompasses all or parts of 16 counties, an area of approximately 18,000 square miles.

The descriptive data for the study area is reported and described at the county level of aggregation. It has been grouped into multi-county sub-regions that roughly coincide with the physiographic regions that have been identified for purposes of the Programmatic Environmental Impact Statement (PEIS) evaluation work. Some of the counties could be considered to be in more than one of the physiographic regions. For purposes of this grouping of data, each county is assigned to only one of the regions. As a result, some regions, for purposes of this presentation of descriptive information, have no counties assigned to them. The multi-county subregional areas are outlined in the following table.

TABLE 2.2-1
LOCATION OF STUDY AREA COUNTIES
BY PHYSIOGRAPHIC SUBREGION

Physiographic Subregion	Study Area Counties
Lower East Coast	Palm Beach Broward Miami-Dade
Florida Keys	Monroe
Big Cypress	Collier Hendry
Caloosahatchee	Lee Glades Charlotte
Everglades Agricultural Area[1/]	[1/]
Upper East Coast	Martin St. Lucie
Lake Okeechobee[2/]	[2/]
Kissimmee	Highlands Okeechobee Osceola Polk Orange

[1/] The EAA is essentially comprised of western Palm Beach County and a small part of eastern Hendry County, but these counties are already being accounted for in other subregions.
[2/] The Lake Okeechobee subregion would likely be comprised of parts of the counties bordering the lake (Hendry, Glades, Okeechobee, St. Lucie, and Palm Beach), but these counties are already being accounted for in other subregions.

Although the study area does not include 100% of each of the 16 counties, the data presented in this section of the appendix cover the full county areas. As described in the discussions about regional economic impacts later in this appendix, a 12 county subset of the study area has been chosen to more realistically represent the economic area of influence for evaluating these regional impacts (it excludes Charlotte, Highlands, Orange and Polk Counties).

E.2.3 POPULATION AND ECONOMY

E.2.3.1 General

Economic and demographic data for the study area, comprised of 16 south Florida counties, can be viewed in a variety of ways. No matter how viewed, the picture which emerges is that of generally higher average incomes than for the rest of the State and Nation, and greater economic and population growth than for the rest of the Nation. This is particularly true of southeast Florida, and while true in terms of the overall study area, some localities do not share in this overall trend. Other key important features of the economic landscape are agricultural activity, fishing, tourism, and recreation. As discussed elsewhere in this appendix, implementation of any of the Comprehensive Plan alternatives being considered in this study will likely have impact implications for all of these areas of economic activity.

The south Florida study area is home to just over 6 million people, about half of Florida's population. This relationship between the study area's population and that of the State has been so for some time and is likely to continue. Population growth tends to exceed the national rate of growth, a trend which continues, although at a declining rate.

Florida's economy is characterized by strong wholesale and retail trade, government and service sectors. Florida's warm weather and extensive coastline attract vacationers and other visitors and helps to make the State a significant retirement destination for people from all over the country. Agricultural production and fisheries are also important sectors of the State's economy, and are especially significant to portions of the study area. While compared to the national economy, the manufacturing sector has played less of a role in Florida, but high technology manufacturing has begun to emerge as a significant sector in the State over the last decade.

Most of the population and economic activity in the study area is concentrated along the Lower East Coast (LEC – Miami-Dade, Broward, and Palm Beach Counties). Per capita income (PCI) for the study area as a whole is above that for the State. The LEC three-county area's PCI is even higher.

Much of the study area's economic profile is similar to that for the State. The profile of the Lower East Coast (LEC) area is likewise similar to that of the overall study area. There are, however, obvious and important differences between individual counties within the study area. Since the majority of the population and economic activity reflected in available statistics is located in the LEC area, the remaining area is by comparison sparsely populated and is the location of important natural environment and agricultural areas, as well as Seminole and Miccosukee Indian Tribal lands.

For a description of the economy to be relevant, it needs to show how the study area relates to the State of Florida and the U.S., as well its distribution within the study area itself. The economy, like the natural ecosystem, is also dynamic and evolves and changes through time. Besides spatial and sector or category-of-activity distribution, change through time is important. The amount of available descriptive data is vast and incomprehensible in raw form. This discussion attempts to reasonably reduce this voluminous body of background information to a meaningful description

E.2.3.2 Population

The 16 south Florida counties which combine to make up the study area had a 1990 population of 6.3 million, accounting for about half of Florida's total. This share has changed very little over the past 20 years, and projections show this proportion to remain somewhat stable over the next 50 years. Over 60 percent of this south Florida population is in the three southeast coast counties of Palm Beach, Broward, and Dade. As with all projections, less certainty can be attached to projections the farther they are into the future. The same is true for estimates for smaller areas as compared with estimates for larger areas. This study's focus is on conditions with vs. without a plan in the year 2050. It is important to realize that there is uncertainty about these projections because they are for a relatively small area, and for a relatively distant future point in time.

Table 2.3.2-1 summarizes the existing and projected population in the study area. The 1990 figures are from the U.S. Census. The future estimates are based on “medium” (there are also “high” and “low” estimates) projections of the Bureau of Economic and Business Research, University of Florida, State of Florida (BEBR) through 2020 (as far into the future as they go), extrapolated to 2050 based on rates of growth exhibited by projections available from the Bureau of Economic Analysis (BEA), U.S. Department of Commerce. The BEA projections used extend to 2040. The 2040-2050 rate of growth is based on an extension of the BEA rate from 2020 to 2040, the last two projection years for the BEA county level projections.

The BEA and BEBR projections, which both contribute to the above projection estimates, are based on different methodologies and assumptions, and as a result, differ in projected growth. In general, the BEBR projections tend to reflect slightly higher growth than the BEA projections for South Florida. In the past, BEBR projections have been closer to actual growth in Florida, and consequently have been used for planning purposes in Corps of Engineers water resource planning studies in Florida. This represents a slight departure from the agency practice of using BEA projections for most feasibility studies and investigations. This practice insures that to the extent projections affect study conclusions, all such studies will have been done using a set of nationally consistent projections.

The small area projections made available by BEA are governed by national and state control totals. The use of BEBR projections instead of BEA projections only marginally affects study outcomes, at the same time making projections used in planning studies closer to the mark. The BEBR county level projections follow the same control total principle at the state level, as that which is used in the county level BEA projections, relative to national and state totals. The BEA county level projections used in this analysis are from "County Projections to 2040" (U.S. Department of Commerce, Economics and Statistics Administration, Bureau of Economic Analysis, Regional Economic Analysis Division, 1992).

The BEBR population projections used in this analysis, from the Florida Populations Studies, Projections of Florida Population by County, 1995-2020 (University of Florida, 1995), represent BEBR's medium range projections (low and high estimates are also developed in BEBR's population studies). In the case of Miami-Dade County, additional adjustments have been made reflecting growth closer to, but slightly below, the BEBR high range estimate. These higher growth trends reflect the anticipated impact of a 1994 United States agreement with Cuba permitting increased immigration from the island. These growth estimates have been made by the Miami-Dade County Planning Division, which has been carefully tracking ongoing growth and immigration trends for the county. It is possible that other counties' future growth will deviate from the set of population projections used in the Restudy. This can be especially so in the case of counties with relatively small populations, such as Hendry, Glades, Okeechobee, and Highlands, for example. Relevant adjustments to the recommended plan can be made as necessary in the future to the extent that underestimation or overestimation of population growth proves to have been the case.

Florida is the fourth most populated state in the nation, with a 1990 estimated 12.9 million total residents. Its past is marked by rapid post World War II growth, which accelerated Florida's share of the U.S. population from just under 2% in 1950 to just over 5% in 1990. This trend is expected to continue, although at a more modest rate, so that about 8% of the U.S. population will be in Florida by 2050. The resulting state population is expected to grow another 75% by 2050, reaching nearly 23 million by then. Growth rates for both the state and the C&SF counties have averaged close to three times the average annual percent growth rates for the U.S. as a whole during recent decades. Future growth rate differences are expected to diminish.

The LEC three-county area comprises about 9.5% of the state's land area but is home to 31% of Florida's population. Population growth is fueled by in-migration, as it continues to be both a leading location for retirement as well as a haven for refugees from such places as Cuba, Haiti, Nicaragua, and Guatemala. By contrast, the group of primarily agrarian counties bordering the shores of Lake Okeechobee (Glades, Highlands, Martin, Okeechobee, St. Lucie, and Hendry Counties, but excluding Palm Beach County), while similar in size to the LEC counties, comprise only about 6% of the study area's population. There is a similar comparison between the LEC subregion and all of the other subregions with the exception of the Kissimmee subregion, comprising just over 20% of Florida's population during the 1990-2050 time period. The Kissimmee subregion's relatively large share of the study area's population, though, is skewed by the inclusion of large urban areas that are actually outside of the study area and outside of the economic area of influence for this investigation, although their counties have been included as discussed earlier. Excluding these areas, the LEC accounts for about 80% of the study area population.

The population growth rate for the south Florida study area is expected to continue to exceed the national rate, but this trend is expected to lessen. By the year 2050, the population of the study area is estimated to still be about half of the State's population of 23 million people. Over 60% of this population is expected to inhabit the three southeast coast counties of Palm Beach, Broward, and Dade. To accommodate this growth, urban development likely will continue. Population growth over the 1990-2050 period is projected to exceed that for the State of Florida as a whole in all but four of the 16 study area counties, two of which (Broward and Dade) are in the LEC.

The following two tables outline the ethnic/racial distribution of the study area population, and the percentage of population over age 65 (1990 Census).

The overall study area racial/ethnic population distribution is similar to that of the State as a whole except that the Hispanic population is significantly higher for the study area than for Florida (20% vs. 12%). Besides being more Hispanic than the State and Nation, the study area population's Hispanic proportion varies greatly by county and subregion (over 49% in Miami-Dade County, and over 27% for the LEC, and less than half the State percent share in most of the Caloosahatchee and Upper East Coast subregion counties, plus Polk County in the Kissimmee subregion). While the white-black distribution is similar for the study area and the State (15% and 14%, respectively), there exists striking variability in this distribution from county to county, and subregion to subregion (92% white in the Florida Keys and Caloosahatchee subregions, to 78% white in the LEC subregion; 95% white in Charlotte County to 72% white in Hendry County). The study area's Native American population as a percent of the total is similar to that for the State (.2% vs. .3%, respectively), both of which are below the percent share for the Nation

(.8%), although there are relatively very high concentrations of this group in the Hendry and Glades County populations (2.1% and 5.7%, respectively). Asian and Pacific Islander population tends to be below the share of the total for the State and Nation in the study area, with the exception of the LEC, where the distribution is similar to the State (1.3% vs. 1.2%, respectively), but below the national average of 3.0%.

There are significantly more people in the over 65 age category in Florida than in the rest of the country (18.4% vs. 12.7%). This trend is exemplified in most counties and subregions of the study area. Most counties and subregions are near, or way above even the Florida average percentage. Only two counties (Dade and Orange), have populations with less than the national average percentage over 65.

E.2.3.3 Economy

The 16-county study area had a 1990 per capita personal income about 8% above that for the State as a whole, while the LEC area (Palm Beach, Broward, and Dade Counties) is about 15% higher than the State's. Florida's per capital personal income is a little higher (less than 1% higher) than for the Nation. About half of the study area's counties have per capita incomes greater than either the State or the Nation. Slightly over half of Florida's employment and earnings takes place in the study area. Nearly two thirds of this is concentrated in the populous LEC three county area. Excluding the northernmost counties of Polk, Orange, and Osceola, which are technically part of the study area, but which realistically fall outside of the main focus of this study, the three-county LEC area accounts for about 80% of most of the statistics of aggregate socio-economic activity for the study area.

Employment and income in the south Florida study area have continued to grow in recent decades at rates about the same as for the State, and about half again faster than the national average. Growth has been significantly greater in the southwest counties and the Florida Keys (taken as a group--Monroe, Collier, Hendry, Lee, and Charlotte), and in the counties around Lake Okeechobee (Glades, Highlands, Martin, Okeechobee, and St. Lucie) than elsewhere in the study area.

As with many of the other socio-economic statistics, the percent of households by county below the poverty threshold varies considerably throughout the study area. Only the Upper East Coast subregion ranks better than both the State and the Nation in this category. All other subregions have some counties above, and some below, this measure of economic well-being, for the State and/or Nation. A majority of the counties in the study area fare better than this percentage for the State and Nation. Four of the 16 study area counties have a higher percentage of households below the poverty threshold than the Nation.

The economy of south Florida is based on services, agriculture, and tourism. While manufacturing has not played a traditionally major role in the economy, this sector has experienced significant growth in recent years. The service industry is associated with the over 65 population which constitutes nearly one-fourth of the residents of Broward and Palm Beach Counties and fourteen percent of Dade's population. These individuals tend to have incomes independent of employment and require additional medical, financial, and household services. This relatively strong services part of the South Florida economy is reflected in percent of total employment and income in the services industry, which is consistently higher than for the State as a whole, which is in turn higher than for the Nation. The exception to this tendency is for those counties whose economic profiles reflect their heavy agricultural orientation, relative to other sectors. For example, in Hendry, Glades, Highlands, and Okeechobee counties, the relative share of farm earnings and employment is roughly 20 to 30 times what it is for the other counties, while the relative share of the services industry tends to be smaller for these counties.

Agricultural production in the region, excluding the Everglades Agricultural Area (EAA), is virtually all in winter vegetables, tropical fruits and vegetables, citrus and nursery crops. Florida is the national leader in citrus fruit production and the manufacture of processed citrus products, accounting for over 80% of the nation's citrus production. Florida is the world leader in the production of grapefruit, accounting for nearly a third of the world's annual supply, and ranks second to Brazil in the world production of oranges, accounting for almost one fifth of the world's supply. Florida produces 100% of the Nation's tangelos and over 95% of its limes. Florida also is the second ranking state in the production of fresh vegetables. South Florida shares significantly in this agricultural productivity. All but three of top thirteen Florida agricultural production counties, as measured by total cash receipts in 1991, are within the study area. And all but two of the study area's 16 counties are in the top half of Florida's counties, as ranked this way.

The EAA economy is based largely on agriculture, the primary focus for the economies of the area's towns of Clewiston, South Bay, Belle Glade, and Pahokee. Besides being the home towns of most of the permanent labor force, they support much of the agriculturally related supply and processing activities and are the headquarters of many of the agricultural enterprises. They also support the industry oriented to serving recreational use in the southern part of Lake Okeechobee. A seasonal influx of agricultural workers increases the population of towns in this area during the vegetable growing and harvesting seasons. This trend used to be more significant when sugar cane harvesting was largely a labor intensive activity. This activity is now mechanized.

Agriculture in the EAA relies on over 500,000 acres of rich muck soils irrigated, drained and under cultivation. On these acres are produced sugarcane, vegetables, sod and rice. Farm employment in the EAA is very seasonal because of the seasonal nature of crop production and harvest activity, although somewhat less so now that sugar cane is mechanically harvested. Year round farm employment is about 4,000 full time employees.

While the vegetables are packed and shipped fresh and are not subject to extensive processing, sugar cane is locally processed which adds considerably to its value and the local output of the industry. Six sugar mills in the EAA process all the cane produced in south Florida, both inside and outside the EAA. All sugar cane is grown under contract for processing at these mills. The mills produce raw sugar, molasses and other by-products. A portion of the raw sugar receives further processing at the sugar refineries located in the EAA. A large portion of the raw sugar is processed outside of Florida.

One of the areas of direct economic impact of the implementation of alternative plans covered in this report is the EAA, where thousands of acres of water storage areas requiring land acquisition would be located, as a part of Comprehensive Plan alternatives. Economic statistics dramatically reveal the especially strong agricultural orientation of the economies of the rural counties bordering Lake Okeechobee. While the majority of the EAA is in western Palm Beach County, it is part of this larger agricultural region. Farm earnings as a percent of total earnings for these counties ranges from 3.3% to 47.2% (3.3% for Palm Beach, 35.2% for Hendry, 47.2% for Glades, 17.9% for Highlands, 16.6% for Okeechobee, 7.6% for St. Lucie, and 8.3% for Martin). By comparison, farm earnings for the United States is only 1.5% of total earnings, and for the State of Florida this figure is 2%. The story is similar for farm employment for these counties. In stark contrast, the economic profiles of Broward and Dade Counties include farm earnings and employment percent shares of totals for these counties far below the State and national averages (less than 1%).

There are also strong per capita income differences between the urbanized LEC and the agricultural areas. Compared to the state and the nation, the LEC counties have larger per capita incomes, while the agricultural counties bordering Lake Okeechobee (with the exceptions of Martin and Palm Beach) have lower per capita incomes.

In the Everglades National Park (ENP) area, small scale agricultural activities existed historically. Much of the marginal land was abandoned from the 1940s to the 1960s, and all agriculture had ceased by 1975. Prior to the official creation of the park in 1947, there existed some small scale lumbering and logging, hunting and fishing. The park's land use activities have been directed at preservation of the natural environment. Some low impact human activities are allowed, involving education, research, and recreation. These activities are the basis for ENP's contribution to the Florida economy.

The economic activity of the Florida Keys/Florida Bay area is somewhat indicated by its land use patterns, which illustrate a predominance of residential activities oriented toward the water and commercial activities along the main (and only) highway. Primary activities in the Monroe County-Florida Keys area are tourism and fishing. Both are related to some extent to conditions in Florida Bay. There has been growing concern that conditions in Florida Bay are worsening. Many observers feel that these changes have been related to decreases in freshwater inflow from the Florida mainland (the Everglades), due at least in part to C&SF Project drainage and flood control features constructed in recent decades.

The relationship between tourism and fishing and the environmental health and vitality of Florida Bay is fairly obvious. These are mainstays of the Monroe County/Florida Keys economy, as reflected by the relative domination of economic activity there in the following sectors: services; retail trade; and fisheries ("agricultural services, forestries, fisheries & other"). Monroe County plays a strong role in Florida's well-developed commercial fishing industry, accounting for about 20% of the State's total in recent years. Shrimp has historically been the most valuable species caught, accounting for over 40% of total sales in the state. There is concern that recent precipitous declines in commercial fish landings in conjunction with degrading conditions in Florida Bay are causally related to these changes, and that continuation of these trends will result in even more fishery declines. Earnings in the economic sector which includes commercial fishing account for nearly 4% of Monroe County earnings, a dramatically higher share than for the U.S., and also significantly higher relatively than for the state overall. Employment in this sector accounts for over 8% of total employment in the county, with similar relative comparisons to the state and nation.

Since 1986, commercial fishing employment has declined by about 10%, with larger declines (50%) in real personal income (i.e., after adjusting to remove the effects of inflation). Much of this drop in fishing activity is in the harvesting of pink shrimp. Some of the decline is likely related to recession, international competition in the shrimp business, and perhaps other causes besides degrading environmental conditions in the bay. But during this period, there have been observations of significant environmental degradation. Estimated total losses in the Monroe County economy over the eight year period from 1986 to 1994 have amounted to about 1% of employment and 2% of personal income.

E.3 MUNICIPAL & INDUSTRIAL WATER DEMAND

E.3.1 OVERVIEW

Two projections of future water consumption for the year 2050 have been made for the Lower East Coast study area. The two scenarios differ in terms of the assumed level of water use conservation. The higher estimate, Projection A, is based on the same percentage distribution and usage of conservation flow devices and irrigation restrictions in effect in 2050 as in 1990. The lower estimate, Projection B, is based on the full implementation of existing federal, state, and South Florida Water Management District mandatory regulations and programs. This lower bound projection scenario represents 100% use and effectiveness of ultra-flow devices by the year 2050.

The higher Projection A estimate for the year 2050 is about 1450 MGD. The lower Projection B estimate is about 1200 MGD, approximately 18% less than Projection A. In this study, the 2050 base condition (the “without-plan” condition) assumes a more moderate application of conservation practices and effectiveness, representing a level of consumption about 12% below the 2050 Projection A estimate.

The principal analytical tool being used to evaluate the alternative plans being considered in this study is the South Florida Water Management Model (SFWMM). This model simulates changes in South Florida hydrology which would result from these alternatives, represented by structural and operational modifications to the Central & Southern Florida Project (C&SF) Project. It simulates a 31 year period of hydrometeorological conditions, using historical data for the 1965-1995 period, to represent a broad range of potential conditions which could be expected to take place over the long run. The outputs of these simulations are used to measure the effects of alternatives being considered in this study.

A major part of the evaluation of alternatives consists of comparing SFWMM output associated *with* a particular alternative in place, with SFWMM output representing conditions *without* the alternative. This comparison of “with-plan” vs. “without-plan” conditions is made for projected conditions for the year 2050. These conditions include an assumed level of water use that is representative of population and economic conditions estimated to exist in 2050.

A key input to this analysis is the estimated water use requirement of the population and economy, in the area covered by the SFWMM, in the year 2050. The SFWMM simulation process estimates as output the demands of this area for agricultural irrigation and for the water management requirements of the C&SF project (salinity control, flood control, etc.). But the municipal and industrial (M&I) demand is required input for running the SFWMM. The 2050 projected M&I water use demands by the residential, commercial, industrial, and public administration sectors of the water using population and economy have been estimated using the IWR-MAIN Water Use Forecasting System.

The basis for the M&I projections used in this study is a water use demand forecast which was prepared under contract for the Jacksonville District, Corps of Engineers, by Gulf Engineers & Consultants, Inc., Baton Rouge, Louisiana (GEC), for specific sub-areas of the SFWMM coverage area. The sub-areas for which these projections are being used in the C&SF evaluations, referred to as Service Areas 1, 2, and 3 (SA1, SA2, and SA3), and the northern Palm Beach County service area, comprise what is widely referred to as the Lower East Coast (LEC), which consists of the populated developed portions of Palm Beach, Broward, and Dade Counties along Florida's southeast Atlantic coast. The 2050 IWR-MAIN demand forecast for these large areas was then converted into specific well withdrawal volumes, conforming to input data format required by the SFWMM.

The northern Palm Beach County service area and SA1 coincide roughly with the eastern developed portion of Palm Beach County, but includes a small portion of northern Broward County. SA2 consists of the rest of Broward County, plus a small portion of northern Miami-Dade County. The demands for SA3, consisting of the remainder of Miami-Dade County, include water demands of the Florida Keys (Monroe County), since water for this area is supplied from SA3 well fields.

E.3.2 SUMMARY OF 2050 M&I DEMANDS BY SERVICE AREA

The Projection A average daily M&I demand for water use in the year 2050 is summarized in ***Table 3.2-1***. The table shows that water use is fairly evenly distributed among the LEC Counties. The Service Areas which coincide mainly with the developed portion of Palm Beach County account for 31 percent of total forecast M&I use, with about 29 percent in Service Area 2, which roughly coincides with Broward County. Service Area 3 use, representing demand in most of Miami-Dade County and the Florida Keys (Monroe County), is somewhat higher in terms of its share of the total.

These 2050 Projection A estimates reflect a level of conservation practices that is the same as estimated to be in place in 1990. That is, the same percentage distribution of the use of restrictive flow devices among all uses in place in 1990 is assumed to be in place for the 2050 usage, and therefore probably can be viewed safely as an upper bound forecast estimate.

TABLE 3.2-1
SUMMARY OF 2050 M&I DEMANDS BY SERVICE AREA – PROJECTION A

Service Area	M&I Demands (MGD)	Percent of Total
Northern Palm Beach County	101.25	7
SA1	349.20	24
SA2	422.24	29
SA3	577.00	40
Total	**1449.69**	**100**

Another set of forecast use estimates, representing 100% use of ultra-flow restrictive devices in place for all consumers by 2050, was also made. The 2050 summary results of this conservation Projection B scenario, which can be viewed as a lower bound forecast estimate, are shown in ***Table 3.2-1***. These conservation projections represent continued implementation of the mandatory federal, state, and SFWMD requirements and programs.

TABLE 3.2-2
SUMMARY OF 2050 M&I DEMANDS BY SERVICE AREA
CONSERVATION PROJECTION B

Area	M&I Demands (MGD)	Percent Reduction *
Northern Palm Beach County	83.66	17.37
SA1	294.18	15.76
SA2	345.72	18.12
SA3	474.80	17.71
Total	**1198.36**	**17.34**

*-From Projection A

The IWR-MAIN forecasts have been categorized by residential, commercial, industrial, public administration, and unaccounted for uses. The percentage breakdown in ***Table 3.2-3*** provides a profile of these uses in the study area for 2050 for Projection A. As the tabulation shows, this profile is generally similar throughout the study area, although residential use is more heavily weighted in southern areas.

TABLE 3.2-3
DISTRIBUTION OF 2050 DEMAND
BY END USE AND BY SERVICE AREA, PROJECTION A

End Use	Northern P. B. County	SA1	SA2	SA3	Total
Residential	47%	49%	56%	58%	54%
Commercial & Industrial	36%	37%	28%	22%	29%
Public & Other	17%	14%	16%	20%	17%
Total	**100%**	**100%**	**100%**	**100%**	**100%**

The demand projections made using IWR-MAIN are made by large areas because the projections are driven by economic and demographic projections, which have been made at the county-wide level. But the SFWMM input requires that the demand input be in the form of well withdrawals, by month, in MGD, spatially identified by grid-cell location, using the SFWMM matrix of 4 square mile (2 mi. x 2 mi.) cells. This information has been developed for existing well pumpages. The conversion of the above projected service area water use into grid-cell based well withdrawal data has been developed using known existing well field locations, and the likelihood of future locations and operations.

The SFWMM runs that are being used for the C&SF Comprehensive Review Study include scenarios for the years 1995 and 2050, and represent both public and private wells. The well withdrawals being used for the 1995 scenario are based on existing known withdrawals, amounting to a total of 803.6 MGD, and represent part (but not all) of the total demand/use in 1995 for the projection area. Excluded are golf course and commercial landscape irrigation (estimated by the SFWMM simulation as a part of the evapotranspiration simulation calculations), deep well withdrawals from the brackish Floridan aquifer, and some other uses which are not consumptive. For example, water is used in rock mining operations, but it is returned immediately after use (consisting mainly of washing rock cuttings), and therefore such use is not really a consumptive use. Instead, it is more representative of moving water from one place to another in the system. Floridan aquifer withdrawals do not represent a withdrawal from the water system modeled by the SFWMM and are outside of the Everglades system.

E.3.3 DEMAND FORECAST METHODOLOGY & PROCEDURES

E.3.3.1 About IWR-MAIN

E.3.3.1.1 Theoretical Basis

Perhaps the simplest approach for predicting future water use is the use of projected gross per capita water use rates and projected population. Gross per capita use can be observed from known water consumption and known population. Projections can be made for different population growth scenarios combined with varying assumptions about future changes in the capita use. such a simplified approach has been found to be inadequate for Corps planning studies and was not used in this study.

IWR-MAIN (Version 6.1), a PC-based software tool used to make projections for water use in this study, is based on observed relationships between water use and causal factors, or determinants, of urban demand for water. Causal relationships have been developed separately for residential and non-residential use. Forecasting relationships used in IWR-MAIN for the residential sector are based on the integration of approximately 60 studies of residential water demand, which contained about 200 empirically estimated water use equations.

For the residential sector, the generalized form of the equation for projected average use is (IWR-MAIN User's Manual and System Description, April 1995, p. D-2):

$$Q = a \; I^{d1} \; MP^{d2} \; e^{(FC)(d3)} \; H^{d4} \; HD^{d5} \; T^{d6} \; R^{d7}$$

where

Q	=	predicted water use in gallons per day
I	=	median household income ($1,000's)
MP	=	effective marginal price ($/1,000 gal)
e	=	base of the natural logarithm
FC	=	fixed charge ($)
H	=	mean household size (persons/household)
HD	=	housing density
T	=	maximum-day temperature (degrees F)
R	=	total seasonal rainfall (inches)
a	=	intercept in gallons/day
d1...d7	=	elasticity values for each independent or explanatory variable

The above relationship can be approximated for any residential subsector, season, purpose (e.g., indoor, outdoor), depending on data availability.

Elasticity is a measure of the relationship between water use and a given explanatory or independent variable. For example, an income elasticity of +0.5 would indicate that a one percent increase in income would result in a .5 percent increase in water use. Some representative sample default elasticities contained in IWR-MAIN are outlined in the ***Table 3.3.1.1-1***.

Table 3.3.1.1-1
Representative Default Elasticities for Residential Water Use Contained in IWR-MAIN

Explanatory Variable	Single Family Summer	Multi-Family Summer
Income	+0.4000	+0.4000
Persons per Household	+0.4000	+0.4000
Housing Density	-0.6500	-0.3000
Marginal Price	-0.2500	-0.1500
Fixed Charge	-0.0015	-0.0010
Maximum-Daily Temperature	+1.5000	+1.2000
Total Rainfall	-0.2500	-0.1000

Forecasting relationships used in IWR-MAIN for the nonresidential sector are based on over 10 years of research on the relationship between employment and water use in over 7,000 establishments representing the eight major industry groups throughout the United States. For the non-residential sector, the generalized form of the equation for projecting water use is:

$$Q = a \; PR^{d1} \; MP^{d2} \; CDD^{d3} \; OTH^{d4}$$

where

Q = water use in gallons/employee/day
PR = labor productivity
MP = marginal price ($/1,000 gal)
CDD = cooling degree days (number of days)
OTH = other (user added)
a = model intercept (gallons/employee/day)
d1...d4 = elasticities for independent/explanatory variables

The above relationship is designed to be approximated by Standard Industrial Classification (SIC) group. While this model is operational within the IWR-MAIN model, the elasticities for all of the explanatory and independent variables are currently set to zero, since there are currently no available elasticities for them. As a result, this version of IWR-MAIN uses a single coefficient equation to calculate water use by industry group for nonresidential use:

$$Q = GED * E$$

where

Q	=	water use in gallons per day
GED	=	gallons per employee per day
E	=	number of employees

E.3.3.1.2 History

The IWR-MAIN system has its origins in work during the 1960's by researchers conducting investigations with the Residential and Commercial Water Use Research Projects at Johns Hopkins University, and for the U.S. Office of Water Resources Research. The original system was called MAIN, which was followed by improvements in MAIN II. These early analytical tools were based on research by Howe and Linaweaver (1967); Wolff, et. al.; and other researchers. The initial system was developed by Hittman Associates, Inc., in the late 1960's.

The U.S. Army Corps of Engineers Institute for Water Resources improved upon the MAIN system, renaming it the IWR-MAIN Water Use Forecasting System, and modifying the model during the 1980's. Ultimately a PC version was created, and new use coefficients and computation techniques were incorporated into the new model based on newly available data and research literature. Improvements continue to be made and are the basis for new updated versions when they are documented and become available for distribution and use.

Current IWR-MAIN development is being accomplished by Planning and Management Consultants, Ltd. (PMCL), of Carbondale, Illinois, under the sponsorship of the Institute for Water Resources, U.S. Army Corps of Engineers; Metropolitan Water District of Southern California; Phoenix Water Services Department; and Illinois Department of Transportation.

IWR-MAIN has been used for forecast studies for a number of major water utilities in the U.S.. Some of these are: Indianapolis Water Company; Phoenix Water and Wastewater Department; Metropolitan Water District of Southern California; El Paso Water Utility; Binghamton, New York; Springfield City Water, Light, and Power; Southwest Florida Water Management District; Las Vegas Valley Water District; and the City of San Diego Water Utilities Department.

E.3.3.2 Data Collection and Model Calibration

Before the water demand forecasting projections can be made, the important steps of utility data collection, and calibration and verification of the IWR-MAIN model must be made.

E.3.3.2.1 Utility Data Collection

Data were collected for 1990 and 1994 from utilities in Palm Beach County (representing approximately 53% of total water use in the county), Broward County (54% of total county water use), and Miami-Dade County (91% of total county water use). Data collection was accomplished with a field survey to obtain the following water data requirements of IWR-MAIN:

- Number of accounts billed monthly by user category
- Quantity of water sold monthly by user category
- Water production by month
- Water and wastewater prices in effect
- Monthly water use for the largest customers
- Water conservation measures in effect

The utility companies in the data collection sample provided detailed data for a large portion of the water usage within the study area, covering a wide area, and including different types of development. For example, data coverage includes areas with high seasonal variations, such as resort areas along the Atlantic coast, highly developed urban and suburban areas, and rural communities. There was a high degree of cooperation on the part of the utility companies in this data collection effort.

E.3.3.2.2 Calibration and Verification of IWR-MAIN Model

E.3.3.2.2.1. Summary

The final result of the calibration and adjustment procedures resulted in a model-produced 1990 estimate for this water demand forecast study area, 913.05 MGD, that is within 2.4 percent of the actual use for that year, 935.52 MGD (U.S. Geological Survey).

IWR-MAIN estimates *demand* (not supply source), and therefore, as shown in ***Table 3.3.2.2.1-1***, the sector breakdown for the IWR-MAIN estimates is categorized by use. The USGS estimates given in ***Table 3.3.2.2.1-2*** are in terms of slightly different use categories, and partly also by supply (i.e., self-supplied vs. utility-supplied). Although the individual breakdown categories may not be completely comparable, the overall totals are. The USGS and IWR-MAIN totals are comparable because *they both represent estimates of total use*, even though the category breakdown formats are different.

Table 3.3.2.2.1-1
Summary of IWR-MAIN Estimated 1990 Water Use For Service Areas Comprising Palm Beach, Broward, and Dade Counties (MGD)**

	Service Area					
Sector	**Northern P. B. County**	**Western P. B. County*** **	**SA1**	**SA2**	**SA3**	**Total***
Residential	23.86	3.20	87.66	150.20	187.79	452.71
Commercial & Industrial	23.64	4.41	86.60	92.45	105.04	312.14
Public & Other	8.43	1.76	30.95	32.82	74.23	148.19
Total	**55.93**	**9.37**	**205.21**	**275.47**	**367.07**	**913.05**

* Totals may not add due to rounding.
** Miami-Dade County demand includes Florida Keys (Monroe County); the Keys are supplied from Miami-Dade County well fields.
*** Western Palm Beach County M&I demand, representing 1% of the total, is not included in the SFWMM calculations.

A good choice for a base year for use in creating an IWR-MAIN forecast is a census year because of abundant socio-economic data availability for model calibration. Hence, 1990, a census year, was chosen to be the base year. The fact that 1990 was a dry year with some mandated water use cutbacks, and the fact that the verification backcast year, 1994, was a wet year without such cutbacks (but with lower irrigation demands), combined to test the predictive capability of the model. As discussed below, the 1990-calibrated model turned out to be a relatively good predictor of 1994 demand. This was due in part to the fact that 1990 and 1994 weather variables, which would be expected to account for some of the variation between the two dissimilar years' consumption patterns, were used to estimate use in 1990 and 1994 in the calibration and verification procedures, respectively. Long term projections through to the 2050 planning horizon used long term average weather variables.

Table 3.3.2.2.1-2
USGS 1990 COUNTY Water Use Estimates*
(MGD)

Use Category	Palm Beach	Broward	Dade**	Total
Public Supply Domestic	112.80	132.25	212.36	457.41
Public Supply Commercial	22.52	28.14	44.33	94.99
Public Supply Industrial	9.59	15.45	30.00	55.04
Public Other	3.24	2.25	6.51	12.00
Public Use	16.47	14.44	32.42	63.33
Public Subtotal	164.62	192.53	325.62	682.77
Self Supply Domestic	21.34	9.60	10.75	41.69
Self Supply Comm/Indust.	32.17	1.63	40.34	74.14
Self Supply Subtotal	53.51	11.23	51.09	115.83
Golf Courses	44.39	21.31	10.39	76.09
Thermoelectric	0.00	0.05	2.26	2.31
Other Irrigation (Comm)	15.61	25.49	17.39	58.49
Total	**278.16**	**250.61**	**406.75**	**935.52**

* Data are from Water Withdrawals, Use, Consumption, and Trends in Florida, 1990, USGS Water Resources Investigations Report 92-4140, and unpublished USGS data.
** Miami-Dade County demand includes Florida Keys (Monroe County); the Keys are supplied from Miami-Dade County well fields.

E.3.3.2.2.2. Residential

Data collected from the utilities surveyed were entered into the IWR-MAIN system, and 1990 use quantities were estimated by the system for the sampled utility service areas. Initial test runs proved that the model estimates are closer to the utility service area estimates when summer elasticity values are used year round. The elasticity values were adjusted appropriately. The calibration procedure involves adjusting the coefficient (intercept) so that the model will estimate the actual water use for 1990.

The next step was to use this calibrated model to estimate 1994 use for the same utility service areas, as a test of model effectiveness. For the sampled utilities for which this initial model was constructed, the overall average residential MGD use predicted by the model was six percent below actual use for the 1994 verification. This differential varied by residential subsector and by season. For such small areas, it is highly unlikely that the IWR-MAIN equations will predict values that are identical to actual values in a verification procedure such as this one for 1994 with a model reflecting 1990 conditions. As a rule of thumb, according to IWR-MAIN procedural guidance, differences in the three to five percent range indicate good performance; differences exceeding 10 percent usually mean further calibration is needed. The 6 percent difference in the verification procedure was deemed to be reasonable, and certainly well below the 10% difference threshold suggesting further calibration.

Additional calibrations were made to reflect residential water use patterns in areas within the SFWMM study area, but outside of the utility service areas whose sampled data was used in the initial calibration. Such calibrations were intended to reflect differences in unaccounted for losses, pumpage vs. treatment quantity differences, and per housing unit water consumption patterns. County-wide 1990 USGS data were used for these additional calibration adjustments. These adjustments helped to make the overall calibration much closer, and enabled extrapolation of water use estimates to the rest of the county areas.

E.3.3.2.2.3. Nonresidential

The nonresidential sector includes commercial, industrial, and public administration use. Model estimation is simply a matter of employment combined with per employee average water use coefficients. These use coefficients exist in the model for the eight major industry groups, and by further more detailed breakdown into employment industry subgroups at the 2- and 3-digit SIC code level. There are 432 such categories of nonresidential water use per employee coefficients available within the version of IWR-MAIN used in this analysis (the most recent available at the time).

A test using Miami-Dade County employment data and nonresidential water use for 1990 was conducted to determine the best SIC level for predicting nonresidential water use. The 3-digit SIC code employment and water use coefficients came closest. While there are no reliable employment projections at the 3-digit SIC code level, the 3-digit water use coefficients were calibrated to reflect the 3-digit code employment mix within each major group in each county, using 1990 data. This calibration produced adequate estimates for 1990 except for Palm Beach County, which required additional adjustments to account for high water use for golf courses, parks, and sports facilities.

E.3.3.2.2.4. Adjusting County Estimates to SFWMM Service Area Boundaries

The economic demand models within IWR-MAIN are driven by independent demographic and economic variables that must be specified for the base year of the forecast (1990) to reflect conditions within the study area. Criteria for selection of a base year are that data must be available for both actual water use, and for the economic and demographic independent variables to be used in the forecast. Most of the required demographic and economic input variables are available from the census, making the latest census year a good choice for a base year. Census employment data is by residence and IWR-MAIN requires employment data by place of work; consequently, other data sources were used for employment.

The SFWMM service area boundaries do not coincide with county boundaries, which required manipulation of the data. This was accomplished by overlaying SFWMM service area maps onto census maps to determine which census block groups and which portions of census block groups fall into each service area. To estimate the portion of each census area included within each service area, census TIGER (Topologically Integrated Geographic Encoding and Referencing system and database developed at the Census Bureau) files were used to develop maps, broken down by block group boundaries, of the counties within the study area. The SFWMM service area boundaries were overlaid onto these maps, allowing land area portions within each block group located within each service area to be identified. For the urbanized developed areas, population and housing data for block groups that straddle service area boundaries were estimated to be in proportion to the area breakdown between different service areas. For the less populated areas, data for block groups bisected by service area boundaries were apportioned in accordance with locations of communities known to be population centers. This was necessary because in such areas it is significantly unlikely that population would be proportional to area. For example, 10 percent of the area of a rural census block group could contain nearly 100% of the population.

For employment, 1990 county estimates were taken from The Florida Long-Term Economic Forecast, Volume 2, State and Local Counties (University of Florida, Bureau of Economic and Business Research, 1995). It should be recognized that this represents a departure from the data presented in the previous section of this appendix. This is due to the fact that at the time the water projections were prepared, the more recent data shown in the previous section were not yet available. The county level data were adjusted to represent SFWMM service area boundaries using the percent of population estimated for each service area at the block group level as a proxy for the employment percentage distribution. Housing types for population in each area were estimated based on known categories from water use data collected from utilities. Household income and persons per household data were based on census county-level data.

E.3.3.3 Projection of Use Estimates to the Year 2050

E.3.3.3.1 Background

The next step was to use the model to estimate water use to the year 2050, using economic and demographic projections. The 2050 use estimate is necessary input for the planning evaluations being used to compare alternatives, which are based to a great extent on SFWMM simulation calculations representing estimated conditions, including M&I water use, in 2050. M&I water use affects plan formulation and recommendations, because of the relationship between M&I water use and the other water needs of South Florida. These effects are incorporated into the SFWMM simulation procedures and calculations, and are reflected in SFWMM output.

As explained previously, the 2050 use estimate is the only *forecast* estimate actually used as input in the SFWMM simulation runs. The simulations which use 1995 M&I demand as input are based on USGS estimates of *actual* use. The 2050 forecast estimate is part of an IWR-MAIN set of projections that include use estimates from the present through 2050. Two sets of projections were made: a high projection (Projection A) based on levels of conservation in 2050 that are the same as now (i.e., no change in intensity of conservation); and a conservation projection scenario (Projection B) based on full implementation of existing federal, state, and SFWMD programs and requirements..

E.3.3.3.2 Projection A

The Projection A demands for selected years are outlined in ***Table 3.3.3.2-1***.

Table 3.3.3.2-1
Projection A – Average Forecast Estimated Total Use
For Indicated Year (MGD)

Service Area	1995	2000	2010	2030	2050
Northern P. B. County	62.02	72.44	88.56	96.39	101.25
SA1	216.02	251.66	306.45	332.82	349.20
SA2	294.99	328.86	380.19	407.13	422.24
SA3	367.36	424.28	511.43	562.82	577.00
Total	**940.49**	**1077.24**	**1286.63**	**1399.16**	**1449.69**

As discussed previously, the IWR-MAIN model verification procedure revealed that for the sampled utilities, the 1994 average residential use as predicted by the model was about 6% below actual use, considered to be reasonable. USGS estimates available for 1995 total actual use, when compared with 1995 model projections for the entire area, differ similarly. The model estimated projection for the 4 service areas, 940.49 MGD, is about 6% below USGS actual use data for 1995, just over 1,002 MGD, for the three county area. Considering that about 1% of the three county area (Western Palm Beach County) use is not included within the projection area boundaries, the model estimate is closer to 5% below actual use.

USGS 1995 actual use estimate data for the three county area is shown in ***Table 3.3.3.2-2***.

In the Projection A estimates, the only increases in use efficiency are due to the effect of the increasing block rate structure used by most utilities (higher price per additional units of water used). Projected future water consumption patterns also change because of changes in the socio-economic profile (employment mix, housing, income, etc.).

Table 3.3.3.2-2
USGS 1995 county Water Use Estimates* (MGD)

Use Category	Palm Beach	Broward	Dade **	Total
Public Supply Domestic	124.85	144.57	245.76	515.18

* Data are from Water Withdrawals, Use, Consumption, and Trends in Florida, 1995, USGS Water Resources Investigations Report 98-4140, and unpublished USGS data.
** Miami-Dade County demand includes Florida Keys (Monroe County); the Keys are supplied from Miami-Dade County well fields.

E.3.3.3.3 Projection B

The conservation Projection B estimates reflect the additional reduction of water consumption by end use water fixtures. IWR-MAIN estimates of water demand per employee and per housing unit include the identification of twenty end uses, such as toilets, showerheads, bathroom faucets, dishwashers, and lawn irrigation. Three categories of use are defined and used in IWR-MAIN: nonconserving, conserving, and ultra conserving. Default values within the model for these three categories of use for toilets, for example, are: 5.5 gallons per flush for *nonconserving* toilets, 3.5 gallons per flush for *conserving* toilets, and 1.6 gallons per flush for *ultraconserving* toilets.

The Projection B conservation scenario use estimates are based on all new construction and remodeling using ultra-low flow water fixtures. Those fixtures included in this conservation scenario are toilets, sink faucets, and showerheads. These projections also assume the gradual changing over to ultra-low flow devices throughout the period of analysis so that by 2050, all fixtures in all units will be ultra-low flow devices. In addition, Projection B includes conservation practices for lawn irrigation designed to achieve a 10% savings between conserving and ultraconserving housing units. These practices are comprised of lawn irrigation allowed only during the period from 5 p.m. to 9 a.m., and the requirement that automatic sprinkler systems be equipped with rain sensors.

Area-specific usage rates for nonconserving, conserving, and ultraconserving fixtures, available from the larger utilities, were used in the projections for the 1990 base year. Otherwise, the IWR-MAIN default values were used. For the four service areas, the assumed levels of end use conservation measures in place in 1990 are outlined in ***Table 3.3.3.3-1***.

Table 3.3.3.3-1
Assumed Distribution of Conservation in 1990
by Housing Type

Service Area	Single Family		Multi-Family		Mobile Home

Total	**2.29%**	**5.25%**	**9.39%**	**14.16%**	**17.34%**

* Extent to which conservation Projection B is lower than Projection A.

E.3.3.3.4 Population and Employment Projections

Water demand forecasts using IWR-MAIN require, as input, projections of housing, employment, and income. Housing projections have been derived from population projections. Population, employment, and income projections are available from the Bureau of Economic Analysis (BEA), U.S. Department of Commerce, and from the Bureau of Economic and Business Research (BEBR), University of Florida, State of Florida. The BEA and BEBR projections are based on different methodologies and assumptions, and as a result, differ in projected growth. In general, the BEBR projections tend to reflect slightly higher growth than the BEA projections for South Florida. The BEBR estimates tend to be closer to actual growth in Florida, and consequently have been used for planning purposes in Corps of Engineers water resource planning studies in Florida. This represents a slight departure from the agency practice of using BEA projections for most feasibility studies and investigations. Consistent use of BEA projections insures that to the extent projections affect study conclusions, all such studies will have been done using a set of nationally consistent projections.

The small area projections made available by BEA are governed by national and state control totals. The use of BEBR projections instead of BEA projections only marginally affects study outcomes, at the same time making projections used in planning studies closer to the mark. The BEBR county level projections follow the same control total principle at the state level, as that which is used in the county level BEA projections, relative to national and state totals.

At the time these water use forecasts were prepared, BEA projections were available at the county level to the year 2040. Available BEBR projections extended to 2005. The BEBR employment and population projections were extended to 2050 using BEA growth rates for these “out” years. This resulted in a BEBR projection higher, but somewhat “parallel” to the BEA projected growth track in the later years of the planning period. The 2040-2050 rate of growth was based on an extension of the BEA rate from 2020 to 2040, the last two projection years for the BEA county level projections. As mentioned previously, it should be recognized that the projections used at the time these water use forecasts were prepared predate the data discussed and referred to in the previous section.

The BEBR population projections used in this analysis, from The Florida Long Term Economic Forecast, Volume 2, State and Counties (University of Florida, 1995), represent BEBR’s medium range projections (low and high estimates are also developed in BEBR’s population studies). In the case of Miami-Dade County, additional adjustments have been made reflecting growth closer to, but slightly below, the BEBR high range estimate. These higher growth trends reflect the anticipated impact of the 1994 United States agreement with Cuba permitting increased immigration from the island. These growth estimates have been made by the Miami-Dade County Planning Division, which has been monitoring ongoing growth and immigration trends for the county.

Estimated population and employment projections for the four service areas used to forecast water M&I demands for the year 2050 are summarized ***Table 3.3.3.4-1***. The basis for the estimates is as described above.

Table 3.3.3.4-1
Projected Population and Employment in 2050,
Florida Lower East Coast Service Areas*

Palm Beach	510,049	593,166	602,503	603,295
Broward	764,949	861,713	857,062	847,897
Dade	1,095,131	1,295,210	1,322,795	1,285,545
Total	**2,370,130**	**2,750,090**	**2,782,360**	**2,736,737**

As mentioned earlier, Monroe County water use is supplied by Miami-Dade County wellfields. Monroe County population is currently just over 80,000, and is projected to reach 125,000 by 2050.

E.3.3.3.5 Average Per Capita Consumption

Per capita rates of use were not used as an input variable in this study, as explained earlier. But the estimated future water use totals can be divided by the population projections for the respective service areas, revealing the resulting average per capita use. ***Table 3.3.3.5-1*** shows the average gallons per capita daily consumption for total average use resulting from the two projection scenarios. There is variation among the different using sectors, and from area to area, but these overall averages provide an indication of the underlying trends resulting from the forecast procedures.

Table 3.3.3.5-1
Average Per Capita Water Use Resulting
From Projections A and B
(gallons per capita per day)

Year	Projection A	Projection B
2000	226	214
2010	228	207
2030	220	189
2050	215	178

E.3.3.3.6 Projections Used in SFWMM Simulations

As discussed previously, the higher Projection A estimates include nominal use efficiencies in the future that represent only the effects of higher prices for incrementally higher levels of water use, and the level of conservation practices already in effect (i.e., with no changes in this pattern/profile of use).

A more realistic future water use scenario would likely include the effects of federal, state, and SFWMD water conservation regulations and policies. The conservation projections (Projection B) discussed above reflect 100% participation in this program by 2050, including full use and effectiveness of ultra-flow devices, and result in forecast water use estimates that are about 18% below the Projection A estimate for 2050. A more moderate application and effectiveness of the practices and techniques that make up the Projection B conservation scenario, would result in about two-thirds of this conservation, or estimated water use about 12% less than the 2050 estimate for Projection A. This level of conservation in use was determined by relaxing some of the assumptions within the IWR-MAIN model, so that less than 100% of fixtures are operating with fully effective ultra-low flow criteria.

In the initial formulation procedure, the Projection A figures were used as SFWMM input. The 12% reduction discussed above, a more credible and more reasonable scenario, was used in the final formulation to represent the 2050 without-plan condition. This level of water consumption and conservation represents the most likely future scenario without implementation of a comprehensive plan resulting from the C&SF Comprehensive Review Study.

E.3.4 COMMENT

These projections are based on fairly reliable relationships between water use and its known causative factors. The confidence of long term projections of such key determinants of water demand as population and employment is diminished the farther into the future the projections are extended , and the smaller the area for which the projections are being estimated. These projections have been made for both a relatively small area, and for a fairly distant future. Although they are best estimates, it is important to recognize their limitations, in view of these observations .

The higher Projection A scenario presumes a continuation of existing use patterns. If conservation practices were to be assumed in the projection scenario, consisting of ultra-low flow devices being in use in 100% of the area by the year 2050, this could result in 2050 forecast demand ranging from 15% to 18% less than Projection A. Both projection scenarios reflect a degree of use efficiency, as discussed above, and as demonstrated by the decline in per capita use during projection period. Such figures and comparisons, while helpful in gaining an understanding of trends, should be viewed with caution since they include water use throughout the economy, and are broad average relationships whose true meaning is limited and perhaps impossible to really fully understand. As mentioned earlier, such simplistic relationships as per capita average use rates are not used in the projection methodology of IWR-MAIN.

Finally, the projection scenario is only one of many possible outcomes for the population and economy of South Florida 50 years from now. The scenario being used is believed to be a reasonable mid-range best estimate of the set of conditions expected to influence water use in the year 2050. Consequently, the resulting estimated future municipal and industrial water use requirements is a reasonable projection to use in this study.

E.4 AGRICULTURAL WATER SUPPLY

E.4.1 OVERVIEW

Agriculture in south Florida generates approximately $3.8 billion in annual economic activity. Agricultural activity in south Florida is concentrated in the Everglades Agricultural Area (EAA), to the south and east of Lake Okeechobee; in basins adjacent to Lake Okeechobee (particularly the Caloosahatchee and St. Lucie Basins); and in rural areas within the coastal basins of Miami-Dade, Broward, and Palm Beach counties. Principal crops include sugarcane, vegetables, tropical fruit, citrus, sod, ornamental plants, and nursery production. Agriculture in south Florida is supported by the region's abundant rainfall – approximately 59 inches along the Lower East Coast and approximately 49 inches in the middle of the peninsula. Unfortunately, this rainfall is not distributed uniformly throughout the year, since the region has distinct wet (May through September) and dry (October through April) seasons. Especially during the dry season, and when precipitation is below normal (i.e., droughts), supplemental irrigation is required for much of the region's agriculture.

During droughts, agricultural water users have higher irrigation water demands, since evapotranspiration is high and soil moisture is not recharged by rainfall. However, during these periods of high water demand, water supplies usually are at their lowest levels. Consequently, water shortage management policies are implemented which restrict use of water so that agricultural water users do not always receive as much water as they would like. Irrigation water shortages can have negative economic consequences for farmers, since water stress can reduce crop yields and can induce crop mortality. Residential water users in urban areas of the LEC can also be subject to water management policies which can limit the use of irrigation water, which is needed for urban and suburban landscaping. These shortages can also have negative economic consequences for landscaping and can result in diminished aesthetics (i.e., brown lawns) and renovation or replacement costs for expired turf or ornamental landscaping.

The Lake Okeechobee Service Area (LOSA), which includes the EAA, is more dependent on agricultural water supplies from Lake Okeechobee than the LEC. During periods of normal rainfall, agricultural – and urban – water users in the LEC have not in the past required significant supplemental water from the lake. In addition to rainfall, the LEC receives significant groundwater recharge via easterly seepage from the Water Conservation Areas under the north-south levee system which serves as a boundary between the LEC and the Everglades. However, during prolonged drought events, significant volumes of water from Lake Okeechobee can be required by the LEC to supplement local water supplies and to prevent saltwater intrusion into wellfields.

The potential effects of five alternative restoration plans (Alternatives A, B, C, D, and the Recommended Plan) on agriculture in south Florida are based on the magnitude and frequency of irrigation water shortages. The net economic effects of the alternative restoration plans are the differences between the expected crop losses resulting from agricultural water shortages under with- and without-project conditions.

The SFWMD has developed an economic post-processor (EPP) to assess the monetary effects of agricultural and urban water supply shortages. The EPP, which is embedded in the South Florida Water Management Model (SFWMM), was designed to estimate the economic losses due to agricultural and urban water supply demands not being met.. The EPP was the principal analytical tool used to evaluate agricultural water supply effects of the alternative restoration plans. The analysis of the alternatives is based upon the profile of south Florida agriculture presented below. The profile includes a description of agriculture in the LOSA and the LEC.

E.4.2 AGRICULTURE IN THE LAKE OKEECHOBEE SERVICE AREA

Table 4.2-1 presents the acreage of irrigated agriculture in the sub-areas of the LOSA, which include the EAA, the Caloosahatchee and St. Lucie basins, and the north shore of Lake Okeechobee. As indicated in this table, there are 742,668 acres of irrigated agricultural land in the LOSA. Agricultural activities in the LOSA sub-areas are described below.

TABLE 4.2-1
IRRIGATED ACREAGE IN THE LOSA

LOSA Sub-Area	Irrigated Acreage
EAA	521,920[1]
North Shore	13,380[2]
Caloosahatchee Basin	138,337[3]
St. Lucie Basin	49,073[4]
Total LOSA	742,668

[4] SFWMD. Long-Range Demands for the St. Lucie Basin. 1997.

E.4.2.1 Everglades Agricultural Area (EAA)

The EAA encompasses an area of approximately 593,000 acres. As indicated in ***Table 4.2.1-1***, the EAA contains approximately 542,000 acres under cultivation. Sugarcane is the dominant crop type, accounting for over 90% of the land under cultivation. The remaining land under cultivation (less than 10%) is occupied by rice, row crops, and sod. Row crops include corn, celery, radishes, and lettuce.

The total EAA acreage in Table 4.2.1-1 does not equal the EAA acreage in Table 4.2-1 for two reasons. First, the two figures represent land use in different years (1995 and 1997). Second, as described below, rice cultivation in the EAA typically serves as a supplemental crop between harvest and replanting of sugarcane. Consequently, the sugarcane and rice acreage significantly overlap.

TABLE 4.2.1-1
AGRICULTURAL LAND USES IN THE EAA

Crop	Acreage	Percent of Total
Sugarcane	485,881	90%
Rice[1]	25,000	5%
Row Crops	16,689	3%
Sod	13,258	2%
Total EAA	541,878	100%

Sources: Hendry and Palm Beach County Tax Appraisers, 1997
[1] IFAS Extension Agent, Palm Beach County.

E.4.2.1.1 Sugarcane

The EAA is very well suited to sugar production. This area provides approximately 22% of total sugar produced in the United States (Lord & Suarez, 1997). In 1989, sugarcane production in the EAA accounted for more than $750 million in agricultural production and 20,000 full-time jobs (Snyder and Davidson, 1994). The EAA has thick organic muck soils and adequate water supplies from precipitation and from Lake Okeechobee via a network of water supply canals. Planting typically occurs in the autumn and winter months. Fertilizer and cane stalks are placed in the furrows, and the cane is sub-irrigated by maintaining a water table depth of approximately 20 inches below the ground surface. While some growth occurs during the winter months, most of the cane growth takes place from May through September. The cane plant will be ready for harvest after approximately 16 months. The harvest season is from October to March. During harvest, the cane is burned to facilitate harvesting. In the last four years, the harvesting of sugarcane in the EAA has become entirely mechanized. The cane is transported by truck or train to one of the seven mills located in the EAA.

Multiple crops can be harvested from a single planting of sugarcane. The root stock is left in place after the first harvest and new growth will arise from the cane stubble. The first regrowth (i.e., ratoon) can be harvested again in another 11 months. Again, the root stock is left in place, and a second ratoon will be ready in another 11 months. Some farms will harvest up to four ratoons, but yields decline with each successive ratoon. After 2-4 ratoons, the stubble is disked out. After harvesting the last ratoon, farmers must decide whether to replant immediately or leave the field fallow until the following autumn. Sugarcane farmers in the EAA typically leave their fields fallow following the mid-winter harvest of the final ratoon until the following fall. Fallow fields are routinely flooded to kill pests and limit soil subsidence. If there is a successive planting, more cane can be harvested the following year. However, if the field is left fallow, yields would be higher once the field is replanted. Many farmers will balance these competing incentives by replanting half of the field and leaving the other half fallow. For this reason, Alvarez (1997) estimates that the following crop distribution would be typical of EAA sugarcane farms at any given point in time: plant cane (25%), first ratoon (25%), second ratoon (25%), fallow (12.5%), and roads, canal, ditches (12.5%).

Sugarcane grown in the EAA is converted into raw sugar and blackstrap molasses at the seven sugar mills found in the area. Sugarcane must be milled rapidly after it has been harvested to avoid degradation of its sugar content. The raw sugar is then shipped to sugar refineries located throughout the United States where it undergoes additional processing. There are two refineries located in south Florida which serve the Florida markets for refined sugar.

E.4.2.1.2 Non-Sugar Crops

As indicated in Table 4.2.1-1, the EAA also supports a variety of non-sugar crops. Most of the non-sugar crops are also grown by sugarcane farmers, who grow rice, vegetables, or sod as supplemental crops. Among the non-sugar crops, rice occupies the most acreage in the EAA. Rice cultivation is small, but it could grow in importance for five reasons. First, rice cultivation is being encouraged by the University of Florida's Institute for Food and Agricultural Science (IFAS) to retard soil subsidence in the EAA. Second, rice production is also recommended by the SFWMD as a way to reduce phosphorus loading into the Everglades, since rice requires less fertilizer than sugarcane. Third, there is already a rice mill in the EAA which has sufficient capacity for increased rice cultivation. Fourth, rice is a good companion crop for sugarcane, since it allows sugar farmers to plant and to harvest a crop of rice during the period in which they would otherwise leave their fields fallow following the final ratoon. Finally, although rice cultivation in the EAA has historically had low profitability relative to sugarcane, world rice prices have been rising in recent years.

Vegetable row crops in EAA are almost entirely winter crops. These crops are primarily leaf crops, such as lettuce, cabbage, parsley, and celery. Many farmers rotate their vegetable cultivation between celery and sweet corn; others rotate lettuce or radishes and sweet corn. In the EAA, vegetables are primarily winter crops, for two principal reasons. First, prices are much higher during the winter months. Second, farmers are able to control soil moisture during the winter months (i.e., dry season) with irrigation. Despite the fact that there are three vegetable packing houses in the EAA, vegetable production in the EAA is limited and will likely remain small. Three primary factors limit vegetable production in the EAA. First, vegetable production has greater risk and uncertainty than sugarcane cultivation. Second, the experience of EAA farmers is with sugarcane cultivation, not with vegetable production. Third, and most importantly, the EAA sugar mills need large inputs of sugarcane to remain profitable. Therefore, the lands owned by the sugar companies will likely remain in sugarcane production as their primary crop. In addition, there are multiple incentives for EAA farmers to grow sugarcane as their principal crops, rather than vegetables. As a condition for membership in the farmers co-operatives, farmers must often provide certain minimum amounts of sugar to the mills, and land leases in the EAA often place limits on non-sugar cultivation.

Sod is grown primarily in the southern portion of the EAA, which is an area of declining suitability for sugarcane due to soil subsidence. Sod production can be economically attractive, since turfgrass sod prices are currently in the range of $0.12 per square foot. Once turfgrass has been planted, it is typically harvested without replanting for the next three to five years. Some farmers harvest more than one crop per year during this period. The sod is harvested in ribbons using oscillating knives which slice off approximately one inch of crown, root, and soil. Approximately 25% of the turfgrass is left behind as seed material (Haydu et al, 1992). The remnant strips are tilled for even distribution in the field. A portion of each field is replanted every five years to rejuvenate the field.

E.4.2.1.3 Soil Subsidence

Soil subsidence (i.e., the reduction of land surface elevation) is an important factor in EAA agriculture. The organic muck soils of the Everglades were formed under anaerobic conditions, and as a result, they are only partially decomposed. The organic matter has formed thick peat soils that overlie the limestone bedrock of south Florida. When organic soils are drained, they subside toward the bedrock as aerobic conditions allow further decomposition (i.e., oxidation) of the organic material. In addition to oxidation, subsidence following drainage is increased by loss of buoyancy, peat shrinkage, fires, and erosion.

In general, the muck soils of the EAA are deeper to the north, near Lake Okeechobee. Consequently, soil subsidence is not as much of a problem near the lake as it is in the southern EAA, where soils are relatively shallow. This advantage for the northern areas within the EAA is reinforced by the climatic influences of the lake, which can help protect crops from south Florida’s occasional frosts. In some southern zones of the EAA, subsidence has reduced the soil layer to less than six inches (the point at which farming is often considered no longer profitable). Another negative aspect of subsidence is that as the soil layer thins, the soil chemistry changes, and the application of additional nutrients (i.e., fertilizer) is required, increasing production costs and decreasing profits from farming.

Historically, the rate of subsidence in the EAA has been approximately one inch per year. Rapid subsidence combined with limited soil depth (to bedrock) has raised concerns about the sustainability of agriculture in the EAA . However, the current rate of subsidence has fallen to approximately 0.56 inches per year (Shih et al., 1997). There are several explanations for the subsidence rate reduction. These include:

- The EAA land-forming program allows higher water tables without crop damage.
- Current varieties of sugarcane, vegetables, and pasture are more tolerant of higher water tables, which limits soil oxidation.
- Farmers are holding more water on their farms as part of phosphorus Best Management Practices (BMPs).
- As land subsides, the same amount of water results in a higher water table relative to land surface elevations.
- Sugarcane has become the dominant crop in the EAA. Cane experiences 70-75% less subsidence than other EAA crops. Sugarcane cover results in lower soil temperatures, which slows oxidation.
- Remaining organic material does not oxidize as quickly as material which has already oxidized.

It appears that reduction in subsidence rates and control of phosphorus releases from the EAA to the Everglades using BMPs are complementary objectives. When subsidence was occurring at the rate of one inch per year, Morris (1975) estimated that oxidation caused the release of 78 pounds of phosphorus per acre per year. This is equivalent to 400% of the average rate of fertilizer phosphorus applied in the EAA (Sanchez, 1990).

E.4.2.1.4 Irrigation Practices in the EAA

The organic (muck) soils of the EAA require careful water management to maximize yields of sugarcane and other crops and to limit soil oxidation and subsidence. Irrigation in the EAA is subsurface, and the soil moisture available to crops depends on the elevation of the water table relative to the land surface. Consequently, EAA farmers carefully manage their water resources to control the water tables on their farms. When water levels are excessively low (for example, during the dry season or droughts) farmers withdraw water from the EAA canal network typically by gravity flow. When water levels are excessively high during the wet season, they pump water from the fields to the canals for drainage.

Farmers in the EAA must consider multiple factors in controlling the water table. Farmers have incentives to maintain high water levels (relative to the surface elevation) in order to: (1) ensure that plants receive sufficient moisture, (2) limit soil oxidation and subsidence, (3) control pests, (4) avert muck fires (which can occur when organic soils become excessively dry), and (5) store water on their farms if shortages of irrigation supplies or downturns in precipitation are expected. Unfortunately, there is an overriding reason for keeping water tables relatively low. Most crops cannot tolerate long periods in flooded soils. If water tables are either too high or too low, the crops become stressed. Crop yields decline, and mortality will be experienced if adverse conditions persist. For sugarcane, farmers balance these considerations and generally attempt to maintain water tables at 20 inches below the surface. If water tables fall, the plant roots will follow the water table downward. If the water levels rebound, crop yields can be reduced, as the plants experience stress from excessive water.

E.4.2.1.5 Land Use in the EAA

EAA land use estimates are incorporated into the SFWMM for 1995 and 2050 and are used in this investigation as the basis for analyzing existing and future with- and without-project conditions. Land use estimates affect most aspects of water management in south Florida, and are critical determinants of the potential economic effects of the Restudy alternatives. The SFWMM applies broad land use categories for agricultural and other land uses in south Florida for two reasons. First, agricultural land uses can be extremely difficult to forecast, since crop types in any given area can change from year to year, and larger scale land use changes – such as the conversion of agricultural land to urban and suburban uses – can occur rapidly as well. As a result, it is more realistic to forecast future land uses with broad land use categories. Second, the 4 square-mile resolution of the model's grid cells is relatively coarse for purposes of assessing the economic value of agricultural water supply impacts of the alternative restoration plans in a localized region.

The SFWMM was designed to simulate the hydrology of south Florida. The SFWMM does not project future land uses, but includes land use projections derived outside the model as input parameters. The model's design considers land use patterns only to the extent that they influence water management decisions. Assumptions about the type of irrigation technology applied to each particular crop (and associated water losses via evapotranspiration) are included in the model for each agricultural land use category.

Agriculture land use designations in SFWMM assign each 4-square mile grid cell to a single crop type, based on the predominant crop located in the cell. Since non-sugar crops in the EAA are spatially diffuse and do not dominate a single cell, only sugarcane is registered under the model's 4 square-mile grid cell resolution. Therefore, the 1995 and 2050 base conditions evaluated in the SFWMM classify all of the agricultural land in the EAA as devoted to sugarcane production. As will be evident later in this report, the model's homogenization of agriculture in the EAA has implications for calculating the economic impacts of the alternative restoration plans.

The acreage devoted to sugarcane cultivation (and agriculture in general) in the EAA under present and future without-plan conditions is expected to decrease from 529,920 acres (1995 condition) to 491,520 acres (2050 condition). The projected decrease is primarily due to the purchase of agricultural land for new Stormwater Treatment Areas. The four alternative restoration plans (A-D) and the Recommended Plan would convert an additional 60,000 acres of EAA sugarcane land to reservoirs to provide additional storage for the C&SF system.

E.4.2.2 Caloosahatchee and St. Lucie Basins

Agriculture in the Caloosahatchee and St. Lucie basins differs significantly from agriculture in the EAA. Soils in these basins are generally sandy, rather than organic (muck). Consequently, irrigation is applied from the surface, and subsidence is not a significant problem.

The sandy soils of the Caloosahatchee and St. Lucie basins also support a different mix of crops than the organic soils of the EAA. Agricultural land uses in the Caloosahatchee and St. Lucie basins are presented in ***Tables 4.2.2-1*** and ***4.2.2-2***. Citrus is the dominant crop type in both basins. The agricultural water needs in these basins that are not met with local sources are met with water released from Lake Okeechobee into these two outlet waterways. The Caloosahatchee basin is an area of expanding agricultural activity with increasing agricultural water demands.

TABLE 4.2.2-1
AGRICULTURAL LAND USES IN THE CALOOSAHATCHEE BASIN IN 1994

Crop	Acreage	Percent of Total
Citrus	78,113 acres	56 %
Sugarcane	50,359 acres	36 %
Vegetables	8,091 acres	6 %
Sod	1,296 acres	1 %
Ornamentals	478 acres	<1 %
Total	138,517 acres	100 %

E.4.3 AGRICULTURE IN THE LOWER EAST COAST

The three service areas of the LEC also contain large areas of agricultural land use. Soil types in the LEC are generally sandy, rather than the organic (muck) soils found in the EAA. Consequently, irrigation is usually applied from the surface, and subsidence is not a significant problem.

The sandy soils of the LEC also support a different crop mix than the organic soils of the EAA. Table 4.3-1 presents the 1995 and 2050 agricultural land use patterns contained in the SFWMM for the LEC service areas, including northern Palm Beach County.

These values were extracted from the SFWMM by the EPP. The EPP considers only those SFWMM land use categories for which economic effects of water shortages can be generated. The EPP uses six broad categories of land use: urban, nursery, golf courses, low-volume (LV) irrigated agriculture (such as citrus and avocados), overhead (OV) irrigated agriculture (such as tomatoes), and other agriculture (including sod, sugarcane, and rice). As suggested in this table, tomatoes are intended to represent truck vegetables grown with overhead irrigation system.

There are significant differences in crop mixes in the three service areas. However, the differences found in this table are understated, since the SFWMM's land use categories are based on irrigation technology and crop water consumption, not crop type. As an illustration of the complexity of LEC agriculture, Miami-Dade County, located in Service Area 3, currently has thousands of acres under cultivation with specialty Cuban vegetables. In addition, Miami-Dade County supports cultivation of over 35 varieties of tropical fruits, with 20 different varieties grown on a commercial scale (Degner et al., 1997).

The categories of urban landscaping and golf courses – which are primarily suburban land uses – are included in the SFWMM as agriculture, since they are maintained with irrigation water that is supplemented directly or indirectly with water from the regional water supply system. While these two land uses are not strictly agricultural, they will be included in the discussions of agricultural water supply throughout this report. As indicated in the National Golf Foundation's National Golf Course Directory, there are 239 golf courses in the LEC distributed as follows, by county: Palm Beach (149), Broward (51), and Dade (39).

Figures 4.3-1 and ***4.3-2*** illustrate the percent changes in agricultural land uses from 1995 to 2050 for each of the three service areas of the LEC, northern Palm Beach County, and the entire LEC. As indicated in Figures 4.3-1 and 4.3-2 (and Table 4.3-1), the three LEC service areas and northern Palm Beach County are anticipated to have large increases in urban land uses between 1995 and 2050. The increases suggest conversion of agricultural land to urban land uses. However, agricultural land use represents less than one-quarter of the land use in the service areas. The land use profile presented in this table is therefore not comprehensive, since the economic post-processor only includes those land use categories for which economic impacts are estimated. This is the reason for the apparent inconsistency in the 1995 and 2050 land use sub-totals shown in ***Table 4.3-1***.

E.4.4 AGRICULTURAL WATER MANAGEMENT DURING SHORTAGES

To estimate the potential damages associated with shortages in agricultural water supply it is necessary to understand (1) how irrigation water supplies are managed during drought periods and (2) how the SFWMM simulates water management during agricultural water shortages. Agricultural water use during droughts is the result of regional decisions made by water management institutions, such as the SFWMD; and local decisions made by water users, including individual farmers. These two levels of water management decision making during droughts are discussed below for the LEC and LOSA.

E.4.4.1 Water Management in the LEC

As described in the preceding chapter, when current or future water supplies are not expected to meet water demands, the SFWMD may institute a series of progressively more severe management measures to conserve water supplies. The SFWMD's Water Shortage Plan provides specific guidelines for water restrictions which are based on the type of use and the severity of the drought. As outlined in the shortage plan, voluntary reductions are initially requested during moderate shortages, but mandatory cutbacks in water use may be required if shortages become more severe.

TABLE 4.3-1
IRRIGATED AGRICULTURAL LAND USE DISTRIBUTION IN THE LEC: 1995, 2050 (in acres)

Land Use	SA1		SA2		SA3		North Palm Beach County		Total	
	1995	2050	1995	2050	1995	2050	1995	2050	1995	2050
Urban Landscape	34,381	58,824	49,866	74,121	61,911	90,015	8,343	15,614	154,501	238,574

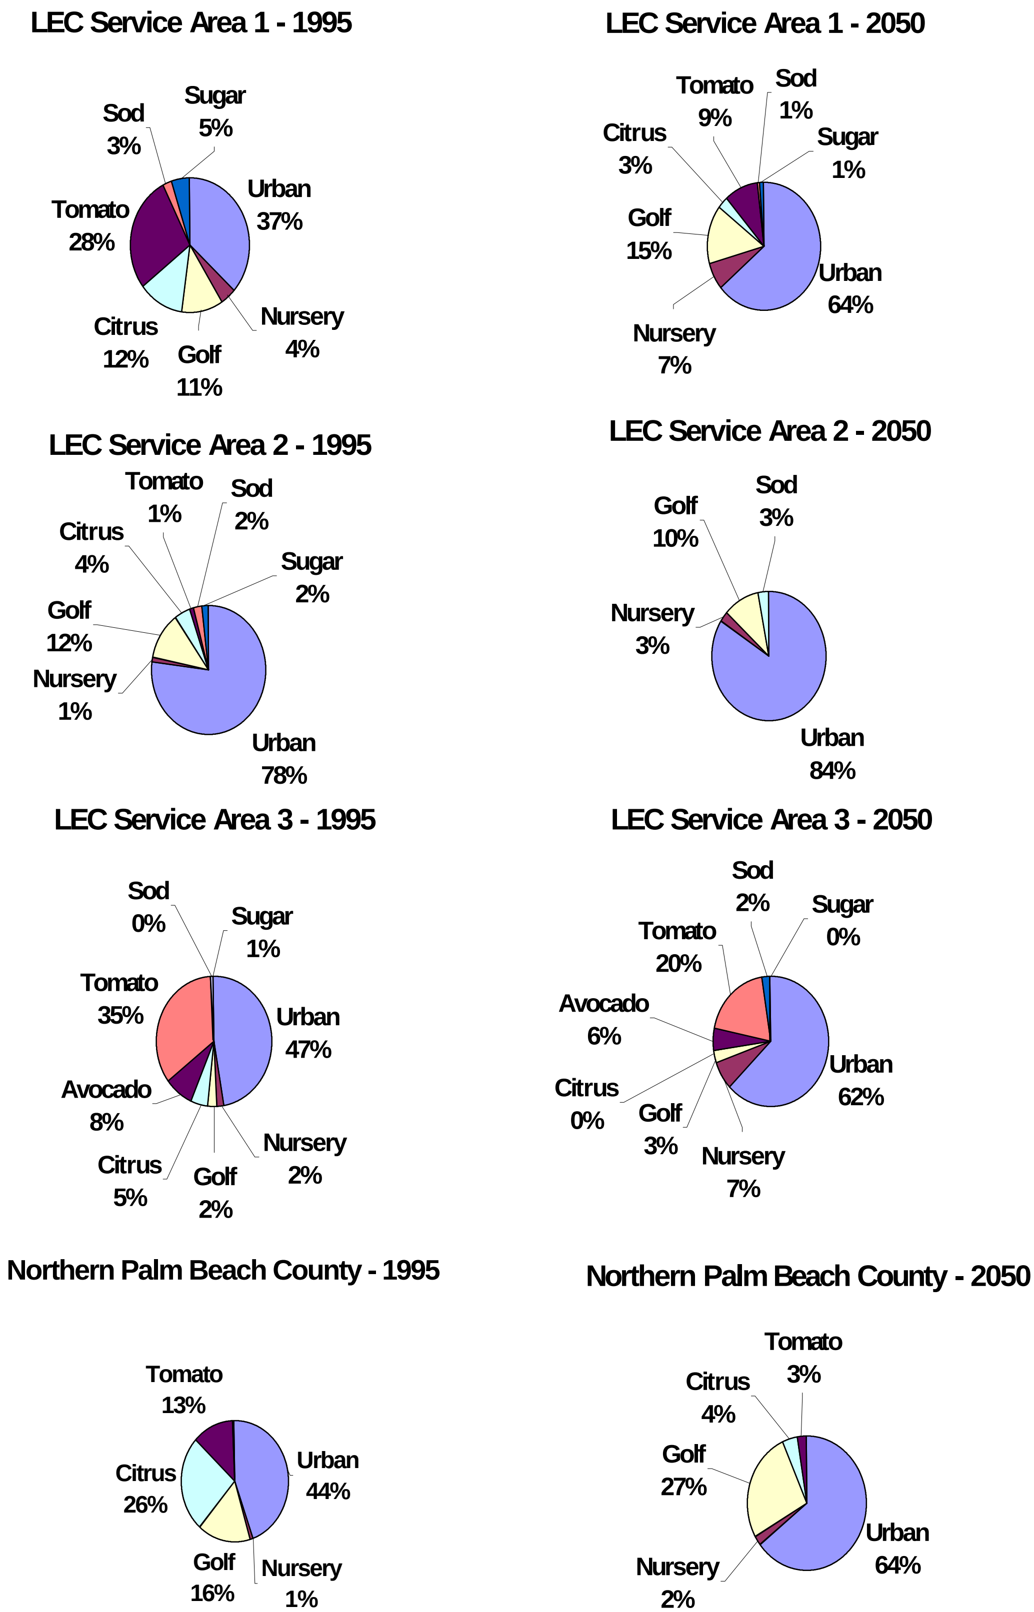

FIGURE 4.3-1
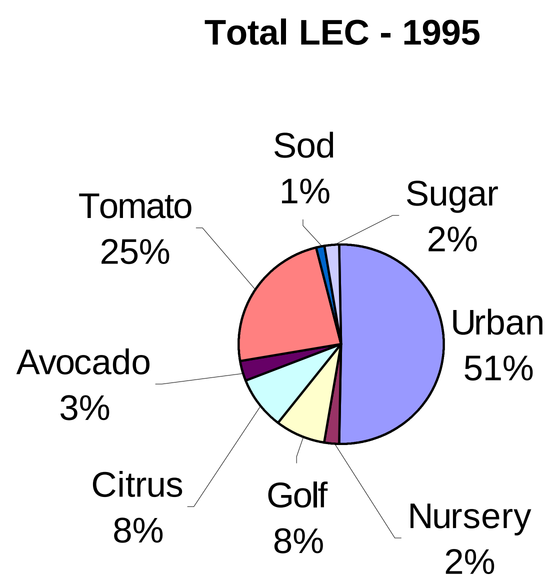
IRRIGATED LAND USE: LEC SERVICE AREAS, 1995, 2050



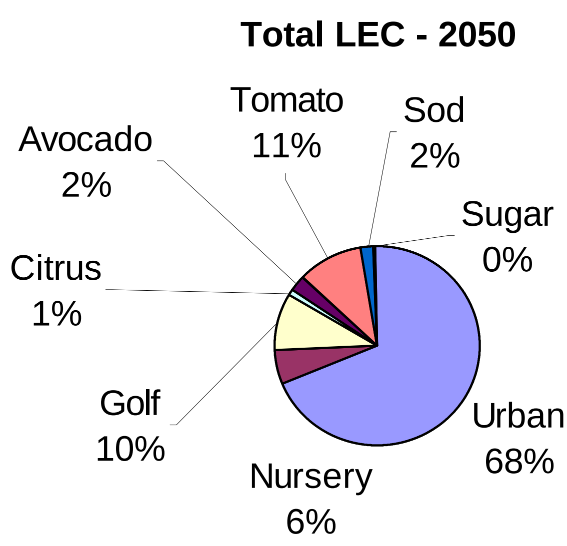


FIGURE 4.3-2
LEC IRRIGATED LAND USE
1995, 2050

The four phases of water supply shortages in the Water Shortage Plan stipulate cutbacks by water users in the LEC, including agricultural and urban water usage. For each phase, the plan stipulates the time of day, time duration, and/or quantity of water usage by irrigation uses, including:

Agriculture	Freeze protection
Crop irrigation	Nurseries
Livestock	Urban irrigation
Aquaculture	Recreation areas
Soil flooding	Golf courses

Agricultural water use is specified by the Water Shortage Plan for each crop type and irrigation method in the LEC. In general, the plan attempts to provide for agricultural water supply needs while progressively reducing water use through the four shortage phases. The water use cutbacks imposed on agricultural water use in phases 1 and 2 are relatively modest compared to those experienced by other water use sectors, such as urban landscaping, golf courses, and recreational areas.

The SFWMM does not model water quality, and groundwater levels are used as surrogate measures of salinity intrusion. In the model, hydraulic head (i.e., water level) is monitored at key trigger wells and canals. When simulated water levels fall below specific thresholds, water shortages are simulated with cutbacks in agricultural water use consistent with ***Table 4.4.1-1***. These are estimates of the water use limitations which may be imposed in each of the phases.

TABLE 4.4.1-1
CUTBACKS FOR SIMULATING AGRICULTURAL WATER USE RESTRICTIONS IN THE LEC

Water Usage or Class	Phase I	Phase II	Phase III	Phase IV
Urban Landscape*	20.0	13.3	6.7	3.3
Nursery	14.5	7.3	4.2	3.0
Agriculture – Overhead	6.1	6.1	3.6	3.6
Agriculture – Low Volume	20.0	20.0	20.0	20.0
Agriculture – Other	20.0	20.0	4.5	3.6
Golf Course	4.8	3.2	1.4	0.6

* For irrigation use, cutbacks represent maximum irrigation application rates in inches/month.

E.4.4.2 Water Management in the LOSA

The phased restrictions in the Water Shortage Plan are not applied to agriculture in the LOSA. Instead, agricultural water users in the LOSA are subject to supply-side management (SSM) for Lake Okeechobee. The required agricultural water use restrictions of the Water Shortage Plan are assumed to have been met when LOSA water users comply with the lake's SSM plan.

During severe droughts, water levels in Lake Okeechobee drop as inflows are exceeded by water losses from releases and evaporation. If water levels fall sufficiently, SSM is instituted for the lake. The amount of water available for use is a function of anticipated rainfall, evaporation, and water needs (for the balance of the dry season) in relation to the amount of water currently in storage. The SSM schedule for the lake is illustrated in ***Figure 4.4.2-1***. SSM begins when lake levels fall below the watch and warning levels and enter Zone A. The upper limit of Zone A represents a storage amount sufficient to meet all demands through the end of the dry season (June 1) provided that all basins receive at least 100% of normal rainfall during that period. Each of the zones represents storage levels with assigned probabilities of shortage. For example, if the stage in the wet season is in Zone A or lower, the area has a 50% or greater probability of exceeding the target allowable lake level established for Lake Okeechobee for June 1 (11 feet).

During periods of SSM, the SFWMD calculates weekly water allocations for each agricultural water user in the LOSA. Available water supplies are estimated based on lake levels, evaporation and rainfall estimates. Allocations are made by comparing normal water requirements with available water supplies.

The SFWMD has allowed EAA farmers substantial flexibility in choosing when to receive their expected allocation during shortages because of the importance of controlling water tables for crop production. Under SSM, water allocations to agricultural users in the LOSA are progressively cutback as shortages become more severe (Zones A to D). However, the SFWMD governing board may allow agricultural users to borrow against their seasonal allocation in the first four months of the dry season. A major reason for borrowing is to maintain yields in sugarcane which will be harvested during that dry season. The behavior of LOSA farmers in the face of water supply shortages is based on the vulnerability of their particular crops to water stress and the value of those crops.

Some crops are more vulnerable to water stress than others. For example, sugarcane is more tolerant to water stress than most vegetables. If sugarcane experiences stress from too much or too little water early in its growing season, the growth of the cane is stunted, and harvest biomass is diminished. However, while crop yields are diminished by water stress, crop mortality of sugarcane only occurs under extremely dry conditions.

Many sugarcane farmers prefer that their crops experience some water stress prior to harvest. If water stress occurs within two months prior to harvest, the biomass will be reduced, but there will also be a desirable increase in sugar content.

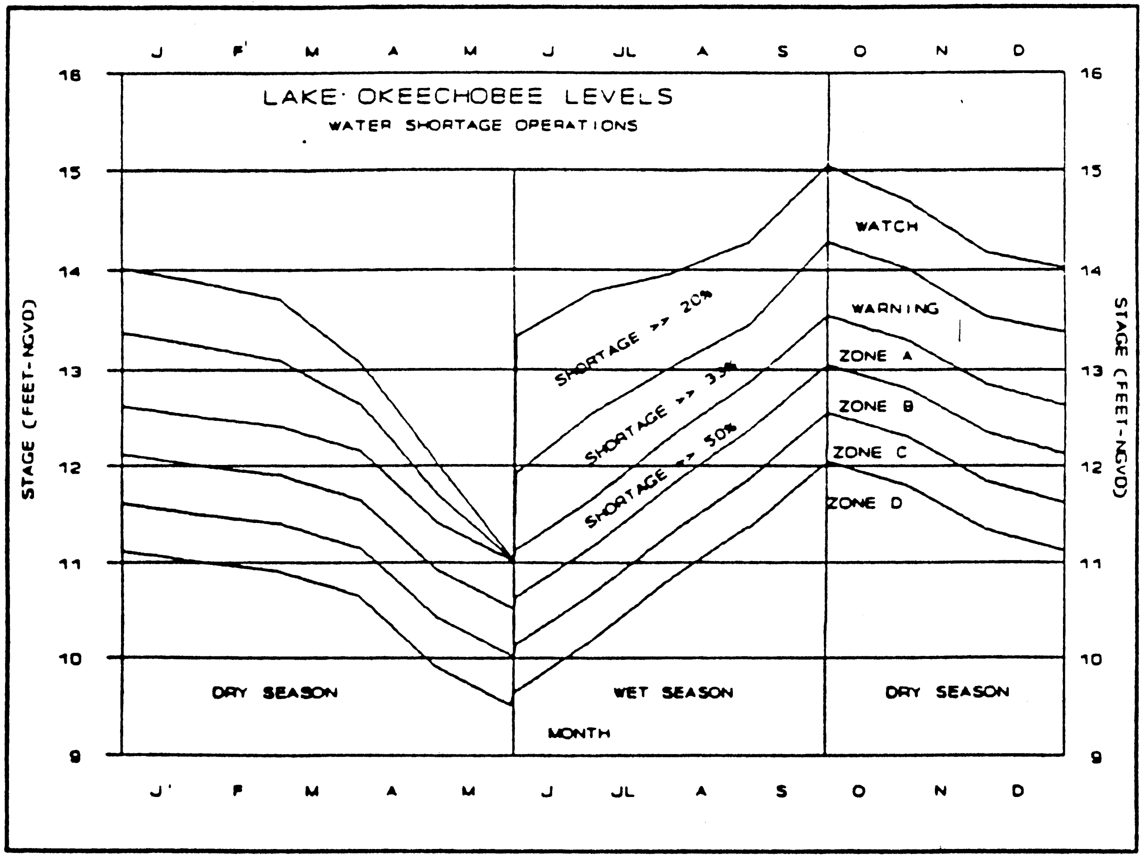

FIGURE 4.4.2-1
SUPPLY-SIDE MANAGEMENT SCHEDULE

Source: Hall, C.A. Lake Okeechobee Supply-Side Management. SFWMD. 1991.

Sugar content can be enhanced by as much as 10% by water stress if it is accompanied by desirable growing conditions (e.g., sunny and cool weather). Some sugarcane farmers prefer to raise or lower the water table to control the amount and timing of water stress prior to harvest. Other farmers prefer to stress the sugarcane chemically. However, this stress must be carefully controlled and timed. If sugarcane is stressed too severely, the reduction in biomass will also be accompanied by a reduction in sugar content, since wilted leaves and dried stalks contain little sugar.

Changes in crop yield are a critical determinant of farm income and can induce changes in crop mix or farming practices. For farmers in the EAA who grow sugarcane and vegetables, decisions during water shortages are based on expected crop-specific responses to water stress and the relative value of each crop. Farmers will allocate water on their lands based upon the greatest marginal value of the scarce irrigation water. Vegetables and sod can quickly suffer large yield effects and crop mortality in response to stress from water shortages. Consequently, when water allocations from the regional water system are reduced, farmers will typically give vegetables, sod, and rice priority over sugarcane (Schueneman, 1997). As a result, vegetables and other non-sugar crops in the EAA are not expected to experience significant irrigation cutbacks during shortages, since sugarcane will be the primary recipient of irrigation cutbacks.

Farmers weigh their present needs against their future needs with careful consideration. The type of crop, timing during the growing season, and anticipated cutbacks are included in their decision making process. Interviews conducted with a variety of experts on EAA agriculture indicate that farmers will generally borrow as much water as they can against their future allocation in order to fully satisfy the water needs of their crops for as long as possible (Alvarez, 1997; Schueneman, 1997). In general, farmers in the EAA will accept the risk of extreme cutbacks later in the season in order to meet their full irrigation needs earlier in the season. Their behavior is supported by experience. During the 1981-1982 drought, widespread borrowing against seasonal water allocations by farmers in the EAA was reinforced by above-normal rainfalls later in the growing season, mitigating the deferred impacts of the drought (Hall, 1991). The SFWMD policy of always meeting at least one-third of the supplemental irrigation requirements of farmers in the EAA may give additional impetus for farmers to borrow against their seasonal water allocations.

Reductions in agricultural water deliveries from Lake Okeechobee to south Florida may or may not actually result in economic losses to farmers. The 1981-1982 experience cited above is testament to this uncertainty. There are a variety of factors which determine the actual economic impacts of shortages, including antecedent conditions, local precipitation during and after the cutbacks, crop types, and the timing of the cutbacks with respect to the growing season.

Interviews with LOSA agricultural experts also suggest that farmers will not significantly modify their production activities during shortages. When shortages do occur, the water stress associated with irrigation cutbacks will result in yield reductions for the entire crop of sugarcane, since water stress will be uniform across the entire irrigated area. Because harvesting activities are entirely mechanized, the unit costs of crop production will not change significantly for different yield levels. Regardless of whether the crop is 100%, 80%, or 50% of potential yield, the costs of crop production will be nearly the same, resulting in a decrease in net farm income nearly equal to the decrease in crop revenues. As will be evident later in this report, this has important implications for estimating the NED impacts of agricultural water supply shortages resulting from the alternative restoration plans.

E.4.5 ECONOMIC POST PROCESSOR (EPP)

The EPP was originally developed to estimate the benefits of structural and/or operational improvements to the regional water supply system by monetizing the "value of unmet demand" for agricultural and M&I water supply. Understanding the concept of "value of unmet demand" is critical to properly interpreting the results of the agricultural water supply analysis. Unmet demand is not synonymous with actual crop loss and is not a direct measure of the impact of alternative plans on reduced crop yields. As stated previously, the AFSIRS model does not predict crop yields, but instead calculates the quantity and frequency of irrigation necessary to avoid water stress to crops.

Value of unmet demand is an estimate of the difference between actual crop yields and values and maximum crop yields and values. As such, the value of unmet demand represents the hypothetical increase in crop yields which could result if farmers were to obtain an amount of water that would not restrict yield. Obviously, such water supplies throughout the year are seldom, if ever, achieved, either in Florida, or in any other farming area throughout the country. The estimates of unmet demand for existing, future without-project, and future with-project conditions are based on a variety of factors, including normal climatic variations, soils conditions, farming practices, and water management system operations (as represented in the 31-year period of record contained in SFWMM). Therefore, the gross estimates of the value of unmet demand contain a variety of factors beyond the control of the C&SF Restudy alternatives, and should be viewed with caution. The proper comparison for this study is the net change in unmet demand between future without-project and future with-project condition, since it "nets out" all of the independent variables except changes resulting from implementation of the Restudy alternatives.

The agricultural element of the EPP was developed through a five-part process as illustrated in Figure 4.5-1 and described below.

E.4.5.1 Development of the AFSIRS Model

The Agricultural Field Scale Irrigation Requirement Simulation (AFSIRS) was developed at the Agricultural Engineering Department of the University of Florida (Smajstrla, 1990). This model predicts water requirements for maximum crop yields. It does not predict crop yields, but instead calculates the quantity and frequency of irrigation necessary to avoid water stress to crops. The program contains the data necessary to model the irrigation requirements of all of the commercially important crops in Florida under various irrigation schemes and with a wide variety of soil types.

AFSIRS calculates irrigation requirements and evapotranspiration rates as a function of crop type, soil type, irrigation system, growing season, and climatic conditions. The model assumes that irrigation requirements are met from the unsaturated zone through rainfall or supplemental irrigation. As illustrated in ***Figure 4.5-1***, the model draws upon four data files. The user specifies three sets of input parameters for the agricultural plot: soils, crops, and irrigation systems. These inputs are combined with time-series precipitation data and simulated potential and crop-specific evapotranspiration rates (PET and ET respectively). The model then calculates how much water is required by the selected crop at a particular point in its growing season under specific soil and climatic circumstances. AFSIRS has been successfully tested and applied in south Florida. The SFWMM contains an AFSIRS module that is used to estimate daily water requirements of irrigated agriculture in the LOSA and the LEC.

E.4.5.2 Modification of the AFSIRS Model for Drought Applications

Thompson and Lynne (1991,a) of IFAS modified the AFSIRS program to estimate changes in crop yield for drought impact analyses. Among the modifications made by Thompson and Lynne was the introduction of the Stewart equation into the model. The Stewart equation relates the difference between actual ET and potential ET (PET) to changes in crop yield. The logical basis for the Stewart equation is that plants reduce their transpiration when they are water stressed, and this reduction is an indicator of stress-induced effects on crop yield. The Stewart equation is as follows:

$$1-(Y_{act}/Y_{max}) = \beta(1-ET_{act}/PET)$$

where:

Y_{act} = actual crop yield per acre (simulated),

Y_{max} = maximum crop yield per acre,

β = crop specific output per irrigation level (Beta coefficient),

ET_{act}= actual evapotranspiration per acre (simulated), and

PET = potential evapotranspiration.

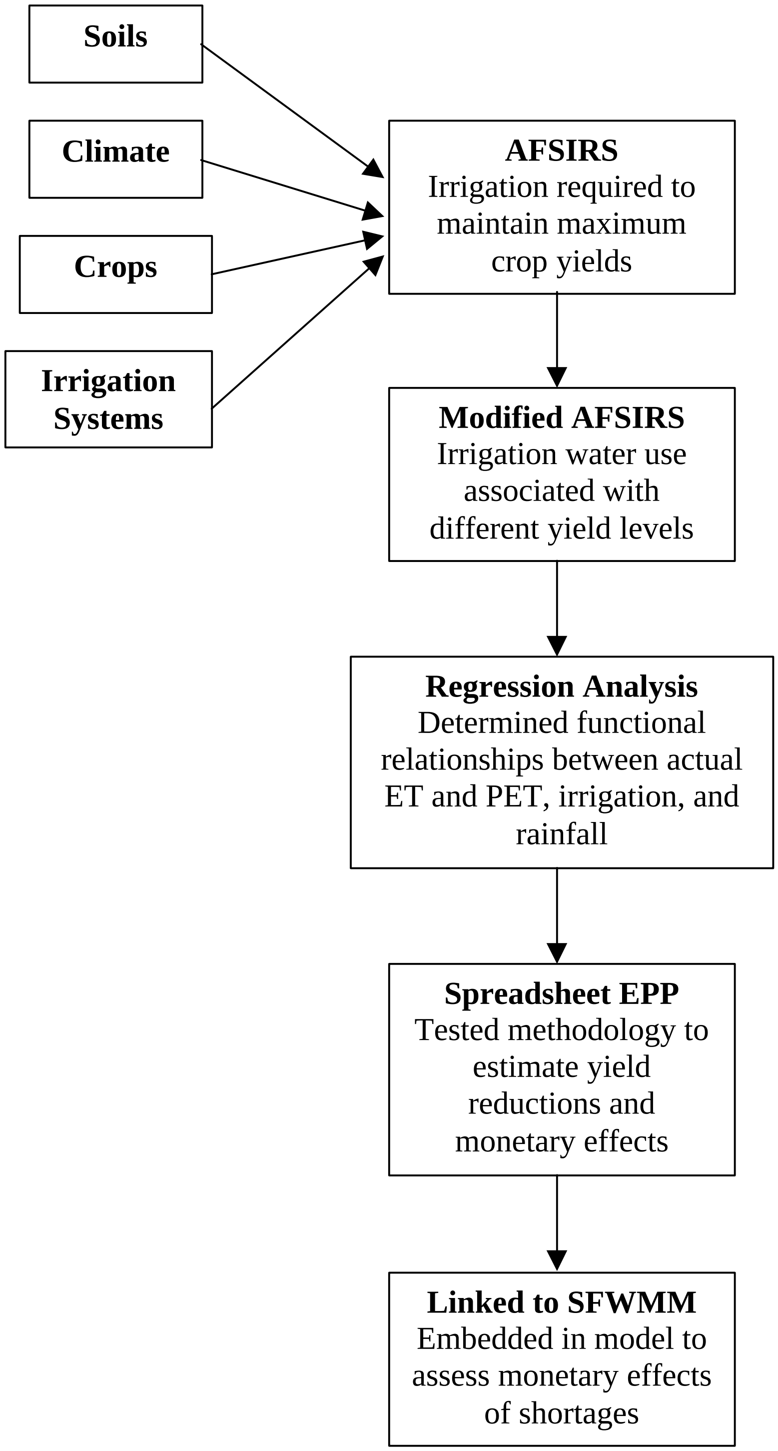

FIGURE 4.5-1
DEVELOPMENT OF THE AGRICULTURAL ELEMENT
SFWMM ECONOMIC POST-PROCESSOR

According to Thompson and Lynne, the Stewart equation is widely accepted. The crop-specific Beta coefficients (β), which relate water stress to crop yields, are based on research conducted for the Food and Agricultural Organization of the United Nations (Doorenbos and Kassam, 1979). The Beta coefficients depend on the crop type and growth stage being modeled. Thompson and Lynne caution users that the Beta coefficients contained in the program have been obtained from experimental data. For annual crops, single coefficients are included in the model for four growth stages: early vegetative, flowering, yield formation, and ripening. For perennials, it is more difficult to produce coefficients for specific growth periods. For example, it is well known that citrus is sensitive to water shortages during flowering. However, the actual flowering period will vary with climate and with soil moisture. This is problematic for AFSIRS, since it calculates irrigation requirements using the calendar date as a key to crop growth stage.

In the modified AFSIRS program, the user must specify actual yields (Y_{act}) as a proportion of the unconstrained yield (Y_{max}). The model uses the Stewart equation to simulate actual ET (ET_{act}). In the model, ET_{act} is drawn from moisture in the unsaturated zone supplied by rainfall or supplemental irrigation. Precipitation estimates contained in the climatic data file are used by the modified AFSIRS program to compute the supplemental irrigation required for the specified crop yields.

Thompson and Lynne (1991,a) attempted to validate the modified AFSIRS program. This was problematic however, since there were no subsequent agricultural droughts with which to compare the model's predictions. Instead, the model was tested against three crop-growth models which have been tested extensively in north Florida. The modified AFSIRS model generated results which were similar to the other models. Improvements were subsequently made to the model during the calibration process.

E.4.5.3 Regression Analysis

The SFWMD used the modified AFSIRS to determine the functional relationships between actual ET and PET, irrigation levels, and precipitation for a wide variety of crop and irrigation schemes (March, 1994). This was done by performing a series of model runs, specifying a range of different actual yields (Y_{act}): 100%, 75%, 60%, 50%, 40%, and 25%. This generated a series of simulated ET_{act} values. Regression equations were then computed to relate modeled monthly ET to monthly PET, rainfall, and net irrigation. The general functional form of the regression equations is double (natural) logarithmic:

$$\ln(ET_{ijkl}) = \alpha + \beta_1 \ln(PET_i) + \beta_2 * \ln(Raadj_i) + \beta_3 * \ln(Iradj_{ijkl})$$

where:

ET_{ijkl} = actual ET in month i of crop j on soil type k for yield level l
PET_I = Modified Penman-Monteith potential ET in month i
$Raadj_I$ = measured rainfall in month i
$Iradj_{ijkl}$ = simulated net irrigation in month i of crop j on soil type k at yield level l

(Note: In this equation, βi= regression coefficients, not the crop output factors in the Stewart equation)

E.4.5.4 Spreadsheet Prototype

The SFWMD developed a spreadsheet prototype of the EPP. During periods when available irrigation water supplies are less than what the AFSIRS model predicts is necessary to support maximum crop yields, the EPP estimates the potential reduction in agricultural revenues using the functions described above. The lower crop yields estimated using the regression functions are compared against maximum yields to determine changes in yield per acre. These values are then multiplied by the number of acres to estimate changes in total crop outputs. Crop outputs are multiplied by market prices to compute the potential revenue effects of water shortages.

E.4.5.5 Linkage to SFWMM

Once the spreadsheet prototype was successfully tested, the SFWMD embedded the EPP within the SFWMM. The SFWMM outputs of PET, irrigation water supply, and precipitation were combined with the agricultural land use profile for input to the EPP. ***Figure 4.5.5-1*** illustrates how the AFSIRS module determines the irrigation requirements for specific crops in particular locations. The EPP compares monthly PET for each grid cell (based on agricultural land use) with available water supply to estimate the monthly restricted ET and the monthly ET reduction from PET. The ET reductions can be used to estimate monthly shortages and crop yield reductions per acre. Reductions per acre are then multiplied by the number of acres and the per acre crop value to estimate the value of unmet demand for agricultural water supply.

According to USDA Natural Resources Conservation Service (NRCS) staff, there was only one drought year during this period, 1982, when there was a significant shortage of irrigation water in south Florida. During this year, crop yields were significantly lower than other years. However, during this year there was also a freeze that resulted in substantial crop damage. Unfortunately, it was not possible to distinguish the effects of the freeze from the effects of the drought. As a result, the results of the EPP have not been tested against historic drought conditions.

E.4.6 EPP ASSESSMENT

The EPP model has some theoretical and experimental components. When the NRCS was supporting the Corps in its attempt to estimate the effects of the alternative restoration plans on agricultural water supply, their staff considered using historical data to develop crop-specific relationships between crop yields and irrigation water shortages. The NRCS reviewed the past 25 years of agricultural water supply data available from the SFWMD and compared this information with historic data on crop yields in south Florida.

The EPP was reviewed to assess its suitability for estimating the NED effects of the alternative restoration plans on agricultural water supply. All five developmental elements illustrated in Figure 4.5.5-1 were examined. First, available AFSIRS documents were reviewed to determine the module's purpose, function, assumptions, strengths, and shortcomings (Thompson and Lynne, 1991,a,b). Second, a copy of the modified AFSIRS program for drought impact analysis was obtained from the SFWMD, including input data files, a copy of the computer code, and supporting documentation. Test runs of the modified program were performed to evaluate program inputs, function, and outputs. Third, the documentation of the regression analyses conducted to develop the functional relationships between simulated ET_{act} and PET, precipitation, and irrigation was reviewed. In addition, SFWMD personnel (Dr. Richard March) involved in developing the EPP were interviewed. Fourth, the spreadsheet prototype of the EPP was examined and tested to evaluate the logic underlying the calculation of the monetary effects of agricultural water shortages. Finally, the draft documentation for the SFWMM was reviewed to determine (1) which SFWMM outputs are used by the EPP and (2) how the AFSIRS module functions within the SFWMM. In addition, the output files from the EPP runs conducted for this investigation were scrutinized to determine how the EPP interacts with the SFWMM.

Based upon this review of the EPP-related materials, the post-processor seems to be a logical and practical approach to a difficult problem, i.e., estimating changes in crop yields and revenues associated with irrigation water shortages. However, there are four categories of issues that qualify the use of the economic post-processor. These issues do not preclude using the EPP to estimate the NED effects of the alternative restoration plans on agricultural water supply, but do qualify interpretation of the EPP outputs.

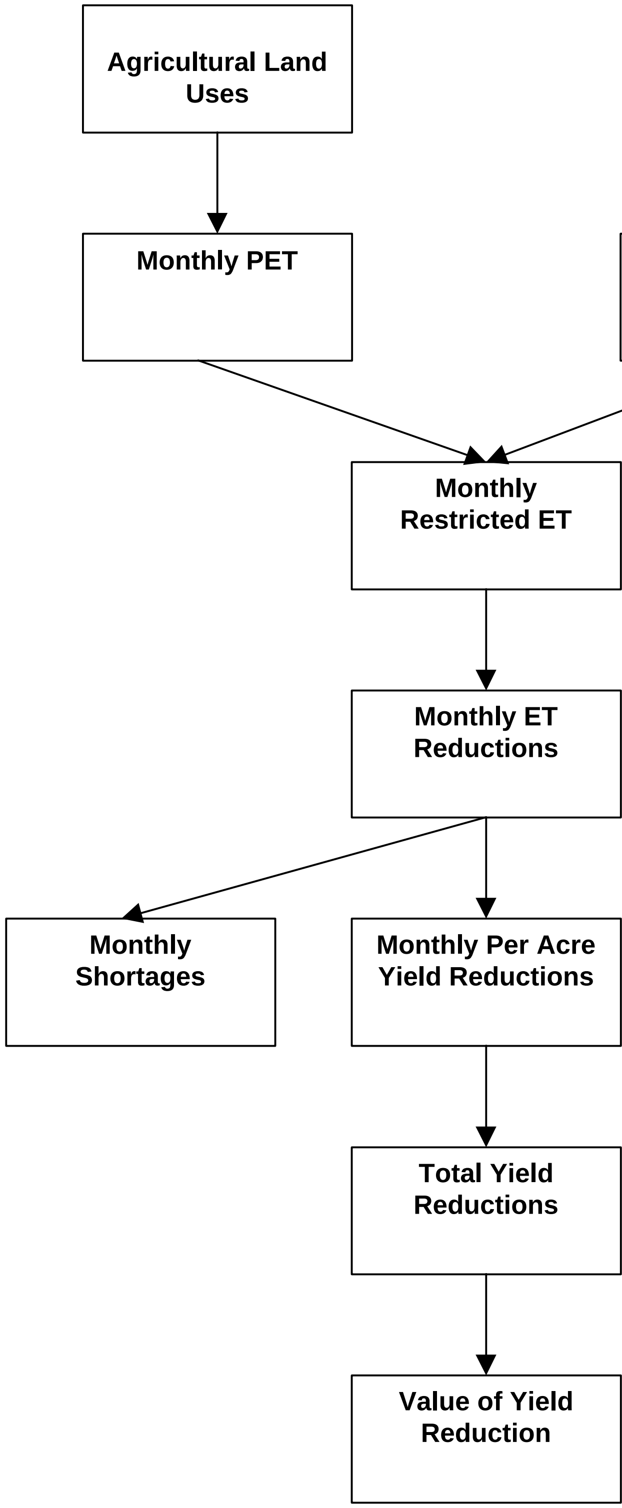

FIGURE 4.5.5-1
CONCEPTUAL FUNCTION OF THE EPP WITHIN THE SFWMM

E.4.6.1 Crop Response

The agricultural science that underlies the AFSIRS model is in its infancy. Although the program has been tested by the SFWMD, and calibrated for use in the SFWMM, the Beta coefficients (crop outputs per irrigation level) used in the Stewart equation are less evolved and should be considered experimental at this time. Additional research is needed to refine these coefficients. This research could determine the sensitivity of crop yields – and revenue effects – to changes in Beta coefficients. The most useful validation of the drought model would be to test it against empirical data from an actual drought event.

It is unclear whether the yield reductions predicted by the modified AFSIRS model imply crop mortality or, in the case of perennials (e.g., citrus), long-term damage that may affect future crop yields. Crop mortality would probably be limited to severe water shortages, but these events may comprise a significant share of potential revenue effects of water shortages. However, the SFWMD has a policy that commits Lake Okeechobee water supplies sufficient to meet at least one-third of the supplemental irrigation needs of EAA farmers. This minimum irrigation level may prevent extensive crop mortality in the EAA during droughts.

E.4.6.2 Growing Season

The timing of agricultural water supply shortages during the growing season is a critical factor in determining the extent and severity of potential crop losses. The difficulty of applying specific Beta coefficients to particular growth stages was mentioned previously. In the EPP, the user specifies the start and end months for the growing season for each crop. The simulation of revenue effects is based upon estimates of yield reductions that would result from water shortages during the specified months. If the actual growing seasons are not well aligned with the modeled growing seasons, the accuracy of the simulation could be compromised. The climate of south Florida is problematic in this regard, since it allows more flexibility in planting and harvesting than more northern climates.

There is an additional complication associated with crop rotation. As described previously, it has been estimated that approximately 12.5% of the land under sugarcane cultivation is fallow at any given time. If this is true, that would remove over 60,000 acres of sugarcane cultivation from vulnerability to water shortages. The EPP does not take crop rotation into consideration and therefore may overestimate the potential damages associated with water shortages. Land rotation considerations might also be important for other crops, as well.

E.4.6.3 SFWMM Constraints

The SFWMM provides tremendous analytical power for evaluating the alternative restoration plans by allowing multiple simulations to compare future with- and without-project conditions. However, there are some model-related constraints that affect its use in estimating the economic effects of agricultural water shortages. First, the land use categories in the SFWMM are broad relative to the complexity of agriculture in the LEC. For example, all of the vegetables grown with overhead irrigation systems are represented by tomato agriculture.

Second, the spatial resolution of the SFWMM is too coarse to accurately assess the agricultural impacts of the alternative restoration plans with great confidence. The grid cell represents only one agricultural use, the most dominant crop within that cell. For example, the SFWMM does not recognize crops other than sugar in the EAA, since none of the 4 square-mile grid cells are dominated by non-sugar crops. In actuality, there could be more than 30,000 acres of non-sugar crops in the EAA.

Third, the model presents a single value for soil depth in a grid cell. In the EAA, the depth of the soil is a critical factor in assessing the drought vulnerability of sugarcane. A single value (i.e., model node) for an area of 4 square miles may mask significant differences in drought vulnerability for the same crop.

Fourth, the full range of potential drought events in south Florida are not represented in the 31-year simulation period. The drought of 1980 and 1981 comprises a large share of the simulated drought effects. If the recurrence interval for this event is greater than once in 31 years, the average annual effects of agricultural water shortages are overstated.

Finally, the model must make assumptions about the behavior of farmers in the LOSA during extended dry periods. The ability of farmers to borrow water early in the dry season creates significant uncertainty regarding the timing and effects of water shortages.

E.4.6.4 Prolonged Water Shortages

The EPP calculates crop yield effects on a monthly basis. For shortages of several months in duration, the EPP may overestimate the effects on crop yield and revenue because each month is treated independently in the EPP. An example may best explain how an overestimation may occur. If there was a water shortage of 20% during the first month of the shortage, crop yields might be reduced by 10%. If the same shortage persisted to the following month, the crop yield effects would again be calculated at 10%. At the end of the year, the shortage would be tallied by the model as reducing crop yields by 20%. However, a 20% shortage sustained over two months might actually result in less than a 20% reduction in annual yield. Even if the 10% value for the second month was correct, it should probably be discounted (i.e., applied to the 90% of yield remaining after the first month of the shortage). One possible way to address this issue would be to treat shortages with durations of multiple months as a single event, evaluating the aggregate water shortage and applying that percentage to the maximum crop yield.

E.4.7 POTENTIAL NED EFFECTS ON AGRICULTURAL WATER SUPPLY

The NED account should reflect changes in net farm income that are associated with reduced agricultural water supply. According to the SFWMM analyses, the five alternative restoration plans will have different effects on agricultural water supply in the study area and thereby have different impacts on farm incomes. For the Restudy, estimating the NED effects of the alternative restoration plans on agricultural water supply requires a four-part analytical process:

- The available water supplies are estimated for each alternative plan.
- The supplies of the alternative plans are compared to water demand forecasts to identify potential shortfalls in water deliveries.
- Identified shortages are translated into yield reductions and then dollar-value reductions in net farm income.
- The monetary costs of water supply shortages of each alternative plan are compared to the costs anticipated in the absence of any action (i.e., comparing the with- and without-project conditions) to estimate the net economic effects of the alternative plans.

The first two steps have been accomplished in the SFWMM using the model's 31 years of daily simulations. The third and fourth steps are addressed below.

E.4.7.1 Revenue And Income Effects

The economic effects of changes in agricultural water supply can be registered in the NED account if there are resulting changes in either crop damages or land use. No land use effects are anticipated for the Restudy, since implementation of any of the alternative restoration plans is not expected to induce any changes in crop patterns. Therefore, the potential NED effects of changes in agricultural water supply are estimated based upon expected changes in net farm income during drought conditions. The NED account should include the net farm income effects associated with changes in both revenues and production costs resulting from plan implementation.

For sugarcane and non-sugar crops, the cost of crop inputs incurred over the course of the growing season would not change significantly during shortages. The potential income effects of water shortages on the cost side would therefore be derived from changes in harvesting and transportation (to processing facilities) costs. For sugarcane, harvesting and transportation in the EAA are conducted by the sugar mills, which then deduct these costs from their payments to the farmers for the cane. Sugarcane harvesting costs would not be expected to change during shortages for two reasons. First, while shortages would reduce sugarcane yields, it is likely that the SFWMD will provide sufficient irrigation water supplies to avoid crop mortality. As a result, the same area would be harvested during shortages as during non-shortage periods, since sugarcane is drought-tolerant. Second, since sugarcane harvesting is entirely mechanized, the combines would harvest the same areas during shortages with costs identical to non-shortage periods.

Under water stress, sugarcane yields in terms of biomass are reduced. Consequently, reductions in transportation costs to the sugar mills are expected. Given the relatively small shortage-induced changes in transportation costs anticipated for sugarcane and the inherent difficulty in quantifying them, it can be assumed for practical purposes that changes in farm revenues are approximately equal to changes in farm income. However, the exclusion of changes in sugarcane transportation costs during shortages may slightly exaggerate reductions in farm income associated with water shortages.

For vegetables and other non-sugar crops in the EAA, the assumption that changes in revenue equal changes in income is valid for other reasons. In the EAA, non-sugar crops such as rice, sod, and truck vegetables are raised by sugar farmers as supplemental crops. Based upon interviews with experts on EAA farm practices, it appears that during shortages, these crops would have irrigation priority over sugarcane. These crops are high-value relative to cane, and they are much more vulnerable to water shortages.

In the LEC, the assumption that changes in revenues would equal changes in income would not be applicable to non-sugar crops (row crops, citrus, etc). There would be some reductions in harvesting costs, as well as reductions in transportation costs. However, based upon a similar analysis conducted for the Lake Okeechobee Regulation Schedule Study, it appears that most of the effects of agricultural water shortages in the LEC are associated with urban landscaping and golf land uses, not commercial agriculture. Consequently, the assumption that changes in revenues equal changes in farm income remains valid for agriculture in the LEC, as well as in the EAA.

E.4.7.2 Crop Prices

Crop prices contained in the EPP come from a variety of sources. Representative prices for agricultural crops (rice, sugar, sod, tomatoes, citrus, avocado, and nurseries) were obtained from the Florida Agricultural Statistics Service (FASS). Representative values for the remaining categories (urban landscaping and golf turf) were derived from the 1992 Water Shortage Economic Impact Model (SFWMD,1990) study conducted for the SFWMD. Urban landscaping and golf turf values are better described as willingness-to-pay values (for green lawns and fairways), rather than market prices.

Corps planning guidance specifies that normalized prices developed by the U.S. Department of Agriculture (USDA) are to be used in water resources planning investigations whenever possible. If normalized prices are not available for a particular crop, average prices for a three-year period are to be used. As indicated in Table 4.7.2-1, the USDA normalized prices for 1997 include three of the EPP crop categories: sugarcane, rice, and citrus (oranges and grapefruit). The prices for rice and citrus were used to modify the EPP outputs. However, to account for significant interstate variability in sugarcane prices, a three-year average price for Florida sugarcane (1994-1996) was used to modify the EPP outputs. The price used for citrus was an average of the orange and grapefruit prices. For fall and spring tomatoes and avocados, three-year averages (1995-1997) were calculated using data from Florida Agricultural Statistics Service (FASS). Sod prices were problematic, since there are very little data available. The sod prices used in the EPP were developed in consultation with University of Florida Professor Haydu, a recognized expert in sod cultivation.

The EPP prices used for golf turf are dependent on the phase of the simulated water shortage. In a 1991 study prepared for the SFWMD by Apogee Research Inc., the costs for golf courses to implement operational changes in response to the shortages range from $9.95/acre (Phase I) to $210/acre (Phase IV). The EPP has the Phase IV value ($210/acre) programmed as the shortage value for all phases, but manual adjustments were made to apply the price appropriate to the shortage phase. Otherwise, there would be significant exaggeration of golf course effects.

TABLE 4.7.2-1
UNIT PRICES USED TO UPDATE EPP OUTPUT TO 1997 VALUES ($)

Crop	Units	EPP Unit Prices	Normalized Prices	Unit Prices Used	Comment
Sugarcane	Ton	$31.12	$28.26	$30.20	3 yr. Avg.
Rice	Cwt.	$10.00	$7.48	$ 7.48	Normalized
Sod	Acre	$3,600.00		$4181.76	Current Prices
Tomatoes – fall	Bushel	$9.35		$7.84	3-year average
Tomatoes– spring	Bushel	$9.35		$7.84	3-year average
Citrus	Box	$4.99-6.63	Oranges - $6.52 Grapefruit-$5.38	$5.95	Average of normalized
Avocado	Bushel	$1.74-41.80		$14.23	3-year average
Urban Landscape	Acre	$3,600.00		$2 per 1000 gallons	Phase I Residential Willingness to Pay
Golf	Acre	$182.00		Variable	Phase Dependent
Nursery	Acre	$7,597.00		$7,597.00	No Change

Market Prices: Florida Agricultural Statistics Service. 1997.

Urban landscaping in the SFWMM includes lawns and landscaping for residential and commercial land uses (golf courses are treated as a separate category). The EPP was originally designed to assign the same unit price to landscaping as used for sod. This would be justifiable if a water shortage was sufficiently severe to extirpate the landscaping and require complete replacement. The SFWMM runs for the alternative restoration plans have not simulated water shortages in the LEC that are more severe than Phase I (moderate shortage). Phase I cutbacks on urban irrigation are modest. The SFWMD Water Shortage Plan (SFWMD, 1991) stipulates that irrigation of urban landscaping during Phase I shortages shall be limited to specific hours of the day and to specific days of the week, depending on the size of the irrigated area. The SFWMM estimates irrigation water uses for urban landscaping during Phase I shortages using maximum irrigation application rates of 20 inches per month. Given these modest effects, an adjustment of the unit price for urban landscaping effects was required. A revised unit price of $2 per 1000 gallons was selected for landscaping effects under Phase I shortages. This price was developed by the SFWMD to estimate the willingness of residential water users in the LEC to pay for water not received under Phase I shortages. For more information about the SFWMD's efforts to estimate LEC water users' willingness to pay for water during shortages, see Section 3 in this appendix on M&I water supply.

E.4.8 EVALUATION OF ALTERNATIVE RESTORATION PLANS

Evaluation of the effects of the five alternative restoration plans on agricultural water supply and revenues in the LOSA and in the LEC includes two principal components. First, the effects on agriculture in the EAA and in the LEC were estimated using the EPP. Second, the effects on agriculture in the Caloosahatchee and St. Lucie basins were estimated separately, using outputs from the SFWMM. These two sets of effects are discussed below.

E.4.8.1 Agricultural Water Supply in the EAA and LEC

Table 4.8.1-1 contains the simulated revenue (and income) effects on agriculture in the EAA and in the LEC associated with existing (1995) and future (2050) without-project conditions and the five alternative restoration plans (A, B, C, D, and THE RECOMMENDED PLAN). The values contained in this table represent the “value of unmet demand” for agricultural water supply estimated for the SFWMM’s 31-year simulation period.

In Table 4.8.1.1, the values of unmet agricultural water demands associated with the alternative restoration plans incorporate reductions in the crop area that are expected to result from plan implementation. For all of the alternative plans, it is anticipated that 60,000 acres in the EAA would be converted from crop land into one or more water supply reservoirs. As a result, in the SFWMM runs conducted for this investigation, the EAA with-project acreage under sugar cultivation was reduced from 491,520 to 431,520 acres.

Average annual values were calculated by distributing the total effects arithmetically over the 31 years. The value of unmet demand is defined as the difference between the normal value of yields under unconstrained water conditions and the value of yields predicted by the model for each restoration plan. As indicated in Table 4.8.1-1, all of the scenarios have unmet irrigation water demands over the simulation period. Considering the severity of some drought events contained in the simulation period (e.g., the 1980/1981 drought), it would be expected that all agricultural water users would receive less than the full amount of water desired from the C&SF system over the 31-year simulation period, except for landscape crops in the LEC. Therefore, the higher the values of unmet demand presented in this table, the greater the reduction in potential yields (and revenue losses) expected under each scenario. As indicated in Table 4.8.1-1, all of the alternative restoration plans have values of unmet demands that are well below those anticipated for the 2050 without-project (base) conditions. This suggests that the alternative plans would improve agricultural water supply conditions relative to future conditions expected with no restoration action. This table includes the effects on urban landscaping and golf turf, as well as agricultural crops.

Table 4.8.1-2 presents the sectoral and spatial distributions of values of unmet demands generated by the SFWMM for the with-project and without-project conditions. The simulated values of unmet irrigation water demand under the alternative plans are limited to golf courses in the LEC and sugarcane in the EAA. The sectoral percentages of total value of unmet demand for each scenario are also presented in this table. As indicated in Tables 4.8.1-1 and 4.8.1-2, sugarcane in the EAA is anticipated to be the agricultural sector most affected by shortages of irrigation water supply. However, all of the alternative plans are expected to represent significant improvements over the without-project future conditions.

Table 4.8.1-3 indicates the differences between the values of unmet agricultural water demand for the simulated with- and without-project futures. The positive (+) signs on the estimates reflect that the alternative plans are expected to be improvements over without-project future conditions. The average annual improvements would be expected to begin soon after project construction and increase up to the levels shown in the table over an assumed 20-year construction period. As indicated in Table 4.8.1-3, the five alternative restoration plans (Alternatives A, B, C, D and The Recommended Plan) have similar performance with respect to agricultural water supply. However, Alternative A is expected to produce the greatest improvement of the five alternative restoration plans with respect to agricultural water supply.

TABLE 4.8.1-1
VALUE OF UNMET DEMAND FOR AGR ICULTURAL WATER SUPPLY
EAA AND LEC, 1995, 2050 SCENARIOS ($1997)

Scenario	Area	Total	Average Annual
1995 Without-Project	EAA	$46,440,533	$1,498,082

TABLE 4.8.1-3
DIFFERENCES BETWEEN SIMULATED
VALUES OF UNMET AGRICULTURAL WATER DEMANDS UNDER
2050 WITH- AND WITHOUT-PROJECT CONDITIONS
($1997)

Alternative	Total Value of Reduced Unmet Demand	Average Annual Value of Reduced Unmet Demands
A	$62,988,090	$2,031,874
B	$53,629,655	$1,729,989
C	$60,390,302	$1,948,074
D	$54,938,370	$1,772,205
Recommended Plan	$58,663,354	$1,892,366

Table 4.8.1-3 indicates that the value of unmet agricultural water demand is expected to increase significantly (from $52,795,890 to $80,894,244) between 1995 and 2050 under the without-project base conditions, respectively. In the absence of structural and management measures that comprise the alternative restoration plans, the performance of the C&SF system in terms of agricultural water supply can be expected to deteriorate over time. The substantial socio-economic and land use changes that are expected to occur in south Florida during the coming decades are among the explanations for this expected decline in system performance.

E.4.8.2 Agricultural Water Supply: St. Lucie and Caloosahatchee Basins

The EPP does not address the Caloosahatchee and St. Lucie basins, but the SFWMM does generate information which is relevant to the evaluation of the effects of the alternative restoration plans within these basins. The EPP was designed for evaluating irrigated agriculture in the EAA and in the LEC. It is directly dependent on the SFWMM for critical inputs, especially evapotranspiration. While the Caloosahatchee and St. Lucie basins are not included in the SFWMM grid cell network, these basins are incorporated in the SFWMM as single model nodes, much like large, individual grid cells. They are important components of the regional water management system for three reasons. First, these waterways provide outlets for regulatory releases from Lake Okeechobee. Second, the basins have water demands – particularly for agriculture – that draw upon the lake's water resources. Finally, the estuaries of these waterways are sensitive to salinity effects of fresh water releases from the lake and the local basins.

Since the EPP can not be used to estimate revenue effects of agricultural water shortages in the Caloosahatchee or St. Lucie basins, the best indicators of agricultural water supply effects of the alternative restoration plans are irrigation water demands and demands not met. The demands not met are presented for the Caloosahatchee or St. Lucie basins in ***Table 4.8.2-1***. These figures include consideration of Aquifer Storage and Recovery (ASR) and reservoirs in the Caloosahatchee basin. As indicated in Table 4.8.2-1, the simulated percentages of demands not met under the 2050 without-project conditions for the Caloosahatchee and St. Lucie basins are 22.4% and 31.6%, respectively. All alternatives appear to represent significant improvements over the future without-project conditions. The Recommended Plan is expected to have performance that is equivalent to Alternative D.

TABLE 4.8.2-1
SIMULATED IRRIGATION DEMANDS NOT MET
UNDER 2050 WITH- AND WITHOUT-PROJECT CONDITIONS

Basin	2050 Base	Alternative				
		A	B	C	D	RP
Caloosahatchee	22.4%	4.1%	6.5%	4.1%	3.1%	2.6%
St. Lucie	31.6%	9.2%	14.9%	9.0%	7.5%	6.7%

Note: RP = Recommended Plan (D13R + Other Project Elements)

E.5 MUNICIPAL AND INDUSTRIAL WATER SUPPLY

E.5.1 OVERVIEW

This chapter examines the potential economic effects of the alternative restoration plans on municipal and industrial (M&I) water supply. It is the first of six chapters that assess the potential National Economic Development (NED) effects of the alternative plans. These chapters examine economic implications of the hydrologic changes that are expected to result from the structural and operational changes to the C&SF project associated with the alternative plans. The hydrologic effects of the alternative plans have been simulated using the South Florida Water Management Model (SFWMM). The model incorporates the M&I water demand forecasts (discussed in the preceding chapter) into the with- and without-project future conditions. The focus of this and subsequent chapters is on the economic significance of hydrologic changes associated with the alternative plans, estimated as the differences between the with- and without-project future conditions.

During droughts, water demands may exceed available supplies. To manage water shortages and protect system reserves, the SFWMD may request and ultimately require water users in south Florida to reduce their water use. Consequently, during water shortages, water users in south Florida may not receive as much water as they would like. Voluntary and mandatory water use cutbacks have economic implications for urban and agricultural users. For urban water users, there may be direct costs associated with the unmet water demands. For example, residential and commercial water users may experience opportunity costs associated with active conservation measures (i.e., reducing water use during shortages). Urban water users may be willing to pay for water not received during shortages to avoid effects on water-related activities such as watering lawns, washing cars, etc. If shortages are frequent, there may be costs to M&I water users associated with: (1) new sources of supply, (2) additional water treatment, and/or (3) more aggressive water conservation. There may also be secondary effects, such as utility revenue losses that are experienced when M&I users reduce consumption during shortages.

This chapter focuses on M&I water use in the Lower East Coast (LEC), since most of the M&I water uses in the SFWMM coverage area portion of the C&SF study area are located in this region. The LEC includes Service Areas (SAs) 1, 2, and 3, which are primarily located within southern Palm Beach County, Broward County, and Miami-Dade County, respectively. Northern Palm Beach County comprises a fourth water supply area.

The discussions of M&I water use in this chapter do not include self-supplied irrigation of urban landscaping (i.e., watering urban and suburban lawns, shrubs, etc) or golf courses. These water uses are included in the discussions of agricultural water supply in the following chapter.

Estimates of the potential effects of the alternative restoration plans on M&I water supply were prepared using the economic post-processor (EPP) developed by the SFWMD. The EPP was designed to assess the economic effects on agricultural and urban water supply anticipated to result from structural and operational changes to the C&SF project.

The assessment of the M&I water supply impacts of the alternative restoration plans begins with a description of south Florida water management during water shortages followed by a discussion of alternative approaches to estimating the economic effects of M&I water shortages.

E.5.2 WATER MANAGEMENT DURING SHORTAGES

The SFWMD monitors hydrologic conditions throughout south Florida. Current hydrologic and water use data are compared to historic data to determine: (1) whether present and future water supplies will be sufficient to meet the needs of water users and (2) whether serious harm to the region's water resources can be expected, including saltwater intrusion into freshwater aquifers or adverse fish and wildlife effects. Factors considered in estimating present and future water supplies include:

- Historic, current, and anticipated levels in surface and ground waters,
- Historic, current, and anticipated flows in surface waters,
- The extent to which water may be transferred from one source to another,
- The extent to which water use restrictions might enhance supplies,
- Historic, current, and anticipated demands of natural systems, and
- Historic, current, and anticipated seasonal fluctuations in rainfall.

Factors considered in estimating present and anticipated water demands include:

- Estimated current and anticipated demands of permitted and exempt users,
- Demands of users whose water supply is established by federal law,
- Anticipated seasonal fluctuations in user demands, and
- The extent to which user demands may be met from other sources.

When current or future water supplies are not expected to meet water demands, the SFWMD may institute a series of progressively more severe demand management measures to conserve water supplies. The SFWMD developed a Water Shortage Plan in 1982 following a severe drought event. The plan provides specific guidelines for water restrictions which are based on the type of use and the severity of the drought. The SFWMD may initially request voluntary reductions, and later require mandatory cutbacks in water use commensurate with the anticipated balance of water supply and demand. Included within the plan is the following sequence of four mandatory water shortage phases:

- Phase I: Moderate Water Shortage,
- Phase II: Severe Water Shortage,
- Phase III: Extreme Water Shortage, and
- Phase IV: Critical Water Shortage.

Shortage declarations by the SFWMD can be triggered by salinity intrusion into coastal aquifers threatening utility wellfields or by low lake levels in Lake Okeechobee relative to seasonal goals. Water shortage declarations are typically made on a monthly basis. However, during the dry season it is likely that the declarations would be continued through the remainder of the dry season, avoiding to the extent possible an on/off whipsaw of shortage declarations that could occur due to short term variability in water supply conditions in South Florida

If droughts are localized, the SFWMD manages the regional water supply system to move water from areas of surplus to areas of deficit. The shortage phase declarations can be scaled to the municipal, utility, county, service area, or regional level, commensurate with the geographic extent of the water shortage. However, declarations are usually applied to entire service areas. For regional droughts such as those triggered by low Lake Okeechobee levels, the water shortage phases can be declared for the entire LEC to reduce water usage in all areas which Lake Okeechobee serves as a backup source of water. The specific use restrictions of the Water Shortage Plan have been invoked three times: in 1982, 1985, and 1989 (Hall, 1991).

The four phases of water supply shortages in the Water Shortage Plan stipulate cutbacks by water users in the LEC, including agricultural and urban water usage. For each phase, the plan stipulates the time of day, duration, and/or quantity of water usage by users in the following use categories:

Essential (e.g. fire fighting)
Domestic
Utility
Commercial
Agriculture
Nurseries
Urban irrigation
Recreation areas, and
Golf courses

The threat of salinity intrusion into the LEC's coastal aquifers is a major water management concern during water shortages. The salinity levels at key coastal monitoring wells are used as triggering mechanisms for declaration of LEC water shortages phases. The SFWMM does not model water quality, and groundwater levels are used as surrogate measures of salinity intrusion. In the model, hydraulic head (i.e., water level) is monitored at key trigger wells and canals. When modeled water levels fall below specific thresholds, water shortages are simulated with the following cutbacks in M&I water use expressed as a fraction of total pumpage: For the 1995 base condition - Phase I (15% cutback), Phase II (30% cutback), Phase III (45% cutback), and Phase IV (60% cutback): and for the 2050 base all alternative conditions – Phase I (10% cutback), Phase II (25% cutback), Phase III (40% cutback), and Phase IV (55% cutback). The latter cutback percentages are lower because of the assumption that conservation measures will have become a part of normal demands in the future.

In the LEC water supply service areas, the overwhelming share of M&I water is supplied to users by local utilities. The utilities draw upon local water resources – primarily groundwater – to meet their customers' needs. When utilities experience shortfalls of water supply, they can augment their supplies or take measures to reduce the demands of their customers.

Supply augmentation can be implemented as short-term or long-term measures. Water supplies can be augmented during short-term emergencies (e.g., large fires), via interutility transfers made possible by utility interconnections. To meet customer demands during water shortages, utilities can draw upon the regional water supply system to augment their supplies. To provide for long-term supply deficits, utilities must develop supplemental sources of water. In south Florida, supplemental water supply sources potentially include:

- Developing additional well fields to tap the relatively shallow Biscayne aquifer,
- Reverse osmosis treatment, or blending (for brackish water from the Biscayne and Floridan aquifers),
- Aquifer storage and recovery, and
- Making wastewater treatment plant effluent available for use after suitable treatment (e.g., advanced wastewater treatment or reverse osmosis).

M&I water demands can be reduced in the short term through active conservation measures during shortages and in the long term by passive conservation measures, such as low-flow plumbing fixtures

E.5.3 ALTERNATIVE APPROACHES TO M&I WATER SUPPLY EVALUATION

The alternative restoration plans could potentially affect the frequency, severity, and duration of M&I water shortages. The conceptual basis for evaluating the economic effects of changes in M&I water supply associated with alternative plans is society's willingness to pay (WTP) for the increase in the value of goods and services attributable to the water supplied. Corps of Engineers planning guidance stipulates that where the price of water reflects its marginal cost, that price should be used to calculate WTP for water supply – in this case, for the amount of water foregone in the supply shortfall. In the absence of such direct measures of WTP, the effects of water supply plans should instead be measured by the least cost alternative (LCA) to replace the shortfall in supply.

The LCA method is widely used in the Corps, given the difficulty of directly measuring WTP for water supply. However, as discussed below, the WTP approach has been selected as the primary method to estimate the M&I water supply impacts of the alternative restoration plans.

E.5.3.1 Problems in Applying the LCA Approach to the Lower East Coast

In the LEC, water supply planning and implementation takes place at the local (i.e., utility) and regional scales. For both scales, the use of the LCA approach in assessing the economic impacts of the alternative restoration plans on M&I water supply is problematic. At the regional scale, there is insufficient information at this time regarding the size and costs of alternative sources of water supply. ***Table 5.3.2-1*** presents a summary of recommendations prepared by the SFWMD for the Draft Lower East Coast Regional Water Supply Plan (1997). These recommendations illustrate the type of water supply measures that are considered to augment regional water supplies. The SFWMD has prepared preliminary cost estimates for some of these measures. Since no capacity estimates were prepared however, estimates of unit costs are not available.

The application of the LCA approach to the LEC at the utility scale is problematic for several reasons. First, the SFWMM-simulated declarations of shortages may not fully reflect the water supply situation of a given utility. Although a utility may have ample water supplies, in the model (and in fact) it could be subject to a simulated shortage declaration if regional monitoring of coastal aquifers indicated potential salinity intrusion. If a shortage was simulated for an entire service area due to salinity intrusion, utilities that effectively manage their water supplies can be penalized along with those utilities that are experiencing supply problems.

Second, the determination of the LCA for an LEC utility during a particular shortage depends on the condition of the regional system. If the shortage is localized, a utility might be able to draw freely upon the regional system, and it may not need to develop supplemental sources of supply. However, if the water shortage is regional in nature, widespread shortages and institutional restrictions may limit access to regional water supplies and reduce supply options available to local water utilities.

Third, there are also practical considerations associated with the large number (29) of utilities in the LEC. Each utility has an array of short-term and long-term options to augment their water supplies. The potential combinations of utilities and options leads to hundreds of possible regional water supply scenarios, which makes the task of assessing the potential effects of the alternative restoration plans extremely difficult.

E.5.3.2 Opportunity Provided by the EPP

The EPP provides an opportunity to efficiently and effectively evaluate the alternative restoration plans using the WTP approach. The SFWMM estimates M&I water supply effects of the alternative restoration plans by comparing M&I water supply with demand. This requires a disaggregation/distribution procedure that accounts for spatial and sectoral uses, as well as groundwater pumpage. In its 31-year simulations, the SFWMM estimates the location, severity, and duration of M&I water supply shortages. It also simulates the frequency and phase of water shortage declarations based on: (1) Lake Okeechobee levels and (2) the salinity intrusion threat to coastal aquifers (estimated using water surface elevations in monitoring wells). These outputs from the SFWMM are then input to the EPP to calculate the economic effects of changes in the level of M&I water supply for each alternative restoration plan.

For each of the water shortage phases, the EPP estimates dollar damages from cutbacks based on the estimated WTP (in dollars per 1000 gallons) of regional M&I water consumers. The SFWMD developed these public water supply loss values on the basis of a 1992 survey of M&I water users in south Florida and also on utility charges for water and sewer services per unit of incremental water use.

E.5.3.3 SFWMD Willingness-to-Pay Survey

The SFWMD survey, which was conducted following regional water shortages in 1989, queried respondents' WTP for water under Phase III and Phase IV reductions. In the survey, residential water users were asked questions about their willingness to pay to avoid water shortages. The questions described in detail how water use behavior would be restricted during Phases III and IV water shortages, including shorter showers, early morning landscape watering, restricted toilet flushing, and possible landscape loss. Respondents asked if they would be willing to avoid these inconveniences and other losses. Specifically, they were told that the SFWMD had a plan that could do away with such shortages entirely, and they were then asked if they would vote for a referendum that would increase water bills to avoid these shortages which otherwise would occur every five years or every 10 years. Respondents were also told that agriculture and industry would pay their fair share.

Each of the Lower East Coast counties was surveyed separately. There were 1,260 respondents to the survey with approximately one-third of the responses each from Palm Beach, Broward, and Dade counties. County-level WTP estimates were developed for the three LEC counties.

SFWMD staff economists estimated WTP values for Phases I and II by subtracting the marginal costs, of M&I water in the LEC on the basis of chemical and power costs of producing and distributing additional water, from the changes in consumer surplus that would result from modest cutbacks in water supply.

Table 5.3.4-1 contains estimates of the WTP (in dollars per 1000 gallons) of M&I water users in the LEC to forgo curtailing water use during water shortages. In this table, the WTP values are presented in 1992 dollars, but for the evaluation of the alternative restoration plans, the WTP values have been updated to 1997 price levels.

E.5.4 ASSESSMENT OF ALTERNATIVE RESTORATION PLANS

The NED benefits of reducing M&I water demands not met are the differences in the consumer and producer surpluses of water use time between the with- and without-project conditions. The EPP calculates the economic value of unmet M&I water demand. The value of unmet demand is based on the amount that M&I customers would be willing to spend to have water that is unavailable during shortages. In the EPP, water supply shortfalls in a given shortage phase are multiplied by the WTP associated with that phase. The values of the unmet water demands during M&I shortages are the basis for comparing the alternative restoration plans against the without-project future conditions.

TABLE 5.3.4-1
WTP OF M&I WATER USERS TO FORGO CURTAILING WATER USE

Source: SFWMD. 1992.

The values of unmet M&I water demand for the alternative restoration plans and the 1995 and 2050 without-project (base) conditions are presented in ***Table 5.4-1***. As indicated in this table, it is anticipated that there will be unmet demand for M&I water supply under both with- and without-project future conditions. The larger the value of unmet demand, the greater the negative effects associated with water shortages. Average annual losses are included in this table, which were calculated as the arithmetic average over the 31-year simulation period. The values in Table 5.4-1 represent the estimated dollar amounts that M&I water users are willing to pay for water they want but do not receive during water shortages. [The expected value of unmet demand for the Recommended Plan is identical to that of Alternative D.]

The value of average annual unmet M&I demand under the without-project future (2050 base) condition ($31.8 million) is significantly higher than the values of unmet demands under existing without-project (1995 base) and with-project future conditions. The differences between the with- and without-project conditions are due to the number and severity of water shortages. ***Table 5.4-2*** presents the number of simulated Phase I water shortages declared during the 31-year simulation period. As indicated in this table, all of the alternative plans are expected to significantly reduce the number of Phase I shortages. The alternative plans have no simulated shortages that are more severe than Phase I. In contrast, the 2050 without-project (base) condition has eight simulated Phase II shortages and one simulated Phase III shortage in addition to the Phase I shortages depicted in the table.

Table 5.4-1 indicates that the average annual value of unmet M&I water demand is expected to increase significantly (from $11.3 million to $31.8 million) between 1995 and 2050 under the without-project (base) conditions, respectively. In the absence of the structural and operational measures that comprise the alternative restoration plans, the performance of the C&SF system in terms of M&I water supply can be expected to deteriorate over time. The substantial socio-economic and land use changes that are expected to occur in south Florida during the coming decades are one of the reasons for the expected decline in system performance.

As indicated in ***Tables 5.4-1*** and ***5.4-2***, the Recommended Plan is anticipated to have superior performance relative to the other alternative plans in reducing M&I water shortages. This superiority is also illustrated in ***Table 5.4-3***, which presents the net effects of the four alternative restoration plans on M&I water supply. Net effects are calculated as the difference between the value of unmet demand under without-project conditions (2050 base condition) and with-project conditions (Alternatives A, B, C, D, and the Recommended Plan). These differences represent the NED effects of the alternative restoration plans. All of the alternative plans have positive net effects, indicating that they would yield improvements in M&I water supply relative to the without-project future conditions. The Recommended Plan is expected to have the greatest positive effects of the alternative plans.

E.6 FLOOD CONTROL IMPACTS OF SELECTED ALTERNATIVES

E.6.1 DESCRIPTION

The Central and Southern Florida (C&SF) Project is a multi-purpose project which provides flood control, water supply for municipal, industrial, and agricultural uses, prevention of saltwater intrusion, water supply for Everglades National Park, small boat navigation and protection of fish and wildlife resources. There have been 5 authorizations since 1948. The primary system encompasses approximately 18,000 square miles from Orlando to Florida Bay and includes about 1,000 miles of levees and canals, 150 water control structures and 16 major pump stations. The Central and Southern Florida (C&SF) Project is operated both by the Federal government and local sponsors. The Jacksonville District has operation and maintenance responsibilities for Lake Okeechobee and its main outlets and the main outlets of the Water Conservation Areas. The St. Johns River Water Management District operates and maintains project features in the upper St. Johns River Basin. The remainder of the project which includes the Kissimmee Basin, coastal canals, and project works in Southern Florida are operated and maintained by the South Florida Water Management District (SFWMD).

For hydrologic evaluation, the Central and Southern Project can be separated into five general subareas. These are the Kissimmee River Basin, Lake Okeechobee Service Area and Everglades Agricultural Area, Water Conservation Areas, Lower East Coast Canals, and Important Environmental Areas.

E.6.2 PURPOSE

The purpose of this section is to attempt to identify the beneficial and adverse flood impacts that might occur with each proposed project alternative. Some of this work has already been accomplished in the formulation of the alternatives. The evaluation in this chapter is limited due to the regional nature of the South Florida Water Management Model (SFWMM) and the resulting lists of impacted areas should be considered preliminary. Subsequent detailed studies will re-evaluate specific flood control aspects of the project alternatives in more detail and revise this list accordingly. In areas where flood hazards are identified or confirmed in this study or subsequent studies, full consideration will be given to improving areas and mitigating impacts by incorporating either design changes or land acquisition.

E.6.2.1 General Methodology

The task will be accomplished in two sections. The first section will describe existing flood damage potential in the basin without any improvements. This section has been developed by conducting interviews with knowledgeable people at the South Florida Water Management District (SFWMD), and the US Army Corps of Engineers. In addition, SFWMD and Corps of Engineers technical publications which describe historical flood events have been reviewed. Areas of concern have been mapped using the SFWMM 2X2 grid cell boundary. The conclusions in this section define existing flood problems and identify flood damage reduction opportunities. Second, information from the SFWMM is reviewed by grid cell for each alternative. Performance indicators for each of the alternatives, Alternative Evaluation Team (AET) concerns, and concerns of other interested parties are then examined to identify potential flooding conflicts. These areas of concern are also mapped using the SFWMM 2X2 grid cell boundary and identified by the appropriate basin. While this investigation will be not be conclusive or quantitative in nature, these areas will be identified for further evaluation in subsequent feasibility reports.

E.6.2.2 Flood Control Evaluation Limitations

The method selected to evaluate hydrologic impacts of alternatives is the South Florida Water Management Model (SFWMM). The SFWMM is a regional-scale computer model that simulates the hydrology and the management of the water resources system from Lake Okeechobee to Florida Bay. It covers an area of 7,600 square miles using a mesh of 2 mile x 2 mile cells. In addition, the model includes inflows from Kissimmee River, and runoff and demands in the Caloosahatchee River and St. Lucie Canal basins. This model is regional in scope and allows for a regional level of evaluation never available before in the planning process. Its use in evaluating performance of alternatives using performance measures and targets has been indispensable for plan formulation. However, like most regional models, the ability to detect and evaluate detailed design problems, especially for flood control, is limited.

Damages to urban development include structural damages to buildings, as well as damages to personal property and associated lawns, pavement, shrubs, and streets. Depth of flooding is the determining factor for damages to structures and their contents. Duration of flooding is the determining factor for damages to lawns, pavement, shrubs, and streets. Flood damages to agricultural development are primarily related to flood duration. Losses to vegetable and fruit crops are very much dependent upon the duration of flooding in root zones. Properly calibrated topographic and stage-hydrograph information is required to compute depths of flooding to structures and duration of flooding to agriculture. Due to the regional design of the SFWMM, this information is not available by 2 X 2 grid cell.

The Central and Southern Florida Project encompasses approximately 18,000 square miles from Orlando to Florida Bay. Much of the area is outside the SFWMM. Areas excluded include the Kissimmee River Basin, and the Upper St. Johns River Basin. Also, the Caloosahatchee River and St. Lucie canal basins are not described spatially. These areas have been excluded from this evaluation.

E.6.3 HYDROLOGIC AND METEOROLOGIC BACKGROUND

In most of peninsular Florida about 60 percent of the annual rainfall normally falls during the four summer months of June through September. Along the southeast coast of Florida the wet season typically runs from June through October. Wet season rainfall is closely associated with convective activity. These rainfall events are normally of short duration and amounts are quite variable spatially. In general, the winter months constitute the dry season and rainfall is associated with mid-latitude systems (fronts and low-pressure centers) and is spatially distributed in a relatively uniform pattern. Even though annual average rainfall is relatively large and the dry season well defined, rainfall over the basin can be quite varied both in annual amount and seasonal distribution.

E.6.4 TROPICAL STORM AND HURRICANE HISTORY

During the typical wet season from May to October, South Florida receives approximately 70 percent of its annual rainfall. Rainfall in South Florida is greatly affected by tropical storms, hurricanes and slow moving low pressure areas which occur almost every year. A chronology of storms that have occurred in recent years is listed below. A publication list which was used to obtain this information is shown in ***Table 6.5.2-1***.

E.6.4.1 January, 1991

Multiple storm-fronts in January 1991 produced extremely heavy rainfall, 11"+ maximum, 6" in the Everglades Agricultural Area. The event happened in the dry season and local growers were keeping water levels high in the canals for irrigation purposes. Soil subsidence has severely affected the performance of the flood control infrastructure in the area.

E.6.4.2 November, 1994

A major rainfall after the 1994 hurricane season occurred during November by the movement of Tropical Storm Gordon up the east coast of Florida. The storm primarily affected the southern central portion of the state. Affected areas included the Kissimmee River Basin, the Upper St. Johns River Basin, the C-111 Basin, as well as the C-102, C-103, C-14, and C-12 basins. Also affected was the Bolles and Cross Canal Basin. Tropical Storm Gordon caused wide-spread flooding of streets and property in central Florida and on the east coast of Florida. The west coast of Florida had no flooding. There were numerous complaints of lake levels being too high in Orange and Osceola Counties with several inquiries as to the SFWMD structures operation. There were also large areas of agricultural land inundated in Central Florida. There were no known cases of residential homes being flooded.

E.6.4.3 December, 1994

A flood event during December 5-20, 1994, affected the east Everglades Agricultural Area (EAA). The area around S-7 received 14” of rain on December 5th. Widespread agricultural flooding occurred in the area. A sod farm was completely destroyed and Okeelanta sugar fields were severely inundated. Several local dikes breached on the Bolles and Cross canal. Alico farm in Hendry County was flooded and Flying Cow Road in western Palm Beach was under water for 3 months. There was flooding in Loxahatchee and C-100A, B, and C were out of banks in selected areas.

E.6.4.4 June, 1995

A severe rainfall event took place on June 18-26, 1995 in the South Dade area. Nine inches of rainfall fell over three days in Homestead, while Miami recorded 11 inches of rainfall over five days. Flows to S-18C prior to the storm were taking place at a rate of around 300 cubic feet per second (cfs). By June 17, flows had increased to 599 cfs. During the storm event, flow from S-18C ranged from 323 to 1,960 cfs. Discharges from S-197 ranged from no flow to 2,565 cfs. Corps projects located in the C-111 basin as well as the C-102, C-103, C-1, C-2, C-4, C-7, C-8, C-9, and C-100 basins were impacted and performed well.

E.6.4.5 Early August, 1995

Hurricane Erin developed in the Caribbean and affected Florida from August 2-5, 1995. Hurricane Erin passed through central and northwestern portions of Florida prior to entering the Gulf of Mexico. Although many portions of the state were affected by the heavy rainfall associated with the storm, they were primarily areas outside of the Central and Southern Florida Project.

E.6.4.6 Late August, 1995

Tropical Storm Jerry affected Collier, Broward, and Palm Beach counties during the period August 23-26, 1995. Over nine inches of rain fell over a period of two days in Palm Beach County. An average of 6.5 inches of rain was recorded in the surrounding areas. Some effects in St. Lucie County were recorded also as the storm came very close to overloading capacity of C-23, C-24, and C-25.

E.6.4.7 October, 1995

Hurricane Opal affected South Florida during October 5-7, 1995. Immediately after, the storm of October 14-19, 1995 affected the South Dade area. Flows at S-18C gradually increased after Hurricane Opal and reached a maximum of 1,540 cfs by October 18. On October 10, the culverts at S-197 were opened, discharging at a rate of 325 cfs. By October 19, the rate had increased to a maximum of 1,509 cfs. Flows then gradually decreased to 248 cfs by November 1, and the culverts at S-197 were closed on November 2nd.

E.6.4.8 September, 1996

Hurricane Fran began in the tropics in September, 1996. The storm traveled up the east coast of Florida and affected Wilmington, North Carolina on September 5, 1996. Hurricane Hortense began as a tropical storm in the Caribbean on September 7, 1996. Although Hortense did severe damage to Puerto Rico, St. Croix, and St. Thomas, the category three hurricane missed Florida and continued up the coast and affected Cape Hatteras, NC.

E.6.4.9 October, 1996

Josephine was an extra-tropical storm which originated about 50 miles southeast of Savannah, Georgia on October 8, 1996 and affected Kinston, North Carolina.

Hurricane Lili originated in the Caribbean on October 16, 1996. This storm made a direct hit on the central Bahamas and feeder bands caused 5” of rainfall in South Florida. However, the storm had no direct impact upon Corps projects. Although the rain was locally heavy, durations were brief and did not result in significant flood problems for the area. The major reason for this reduced impact was that the South Florida Water Management District (SFWMD) had drawn down coastal canals in advance of the hurricane. There were reports of some flooding problems in some low lying and poorly drained areas of Dade and Broward counties. Water levels were also high in the area known as the “8.5 Square Mile Area” located west of Levee 31 North adjacent to Everglades National Park.

E.6.4.10 November, 1996

Hurricane Marco developed in the Caribbean on November 19, 1996. The storm had no direct flooding impact upon Corps projects, but caused beach erosion and wind damage primarily south of Vero Beach.

E.6.4.11 January, 1997

South Florida Storm (January, 1997) - Caused beach erosion and wind damage.

E.6.4.12 July, 1997

Hurricane Danny began in the Caribbean in July, 1997. This storm originated southwest of Mobile and caused flooding primarily in Mississippi and the Florida Panhandle area.

E.6.4.13 September, 1997

Hurricane Erica began in the Caribbean in September, 1997. This storm went northeast of the United States.

E.6.5 EXISTING FLOOD DAMAGE POTENTIAL

E.6.5.1 General

The purpose of this section of the evaluation is to identify areas in the C&SF basin where a potential problem could occur without any project modifications or could occur if alternative plans increase stages or durations of storm events in the area. Generally speaking, the C&SF Project operates well for flood control purposes within the original design limitations that were formulated when the project was constructed. In addition, the Corps of Engineers, in partnership with the SFWMD, has re-evaluated many project components during the project life to reassess their effectiveness when changing needs have occurred. Federal funds for the modified components were proposed for construction when economic justification was demonstrated and allocated, subject to federal funding priorities. The SFWMD has assisted with non-federal funding, and has implemented discharge rules and other non-structural measures to limit runoff and decrease the need for future water resource modifications. Some of the project features that have been reevaluated include, but are not limited to, the Upper and Lower Kissimmee River Restoration, West Palm Beach Canal, The South Dade Conveyance Canals including C-111, and Modified Deliveries to Everglades National Park. Project features currently being evaluated include Bolles and Cross Canals, and Canals 7, 8, and 9. Rehabilitation to Corps of Engineers structures has also been authorized after severe storm events such as Hurricane Andrew.

Despite extensive efforts to keep the project current, operation of the project has become more difficult due to unexpected urbanization in some areas causing increased flows above design, urban encroachment into canal rights of way, regulatory problems with permitted discharge restrictions during long duration storm events, and conflicting environmental, urban, and agricultural issues. These sensitive areas where the potential for problems exist are the focus of this section. The identification of these areas without project modifications do not include areas where the problem is that secondary drainage is inadequate or not maintained. In addition, historical flood damages caused by storms that are greater than the project design in any of the C&SF basins are not considered a design problem.

E.6.5.2 Identification of Problem Areas

Areas of concern were identified primarily from the review of SFWMD technical publications listed in ***Table 6.5.2-1*** and discussions with Corps of

Engineers and SFWMD officials. Two sets of GIS maps at a scale of 1:100,000 were generated. Both sets include the C&SF basin outline, the 2X2 mile grid overlay, county overlays, hydrologic sub-basin overlays, roads, towns and railroads, lakes, water control structures and canals. In addition, one set of maps includes generalized 1995 land use information. The other set includes SFWMD water use permits for agriculture in the EAA. It was possible using these data to identify potential problem areas in the basin and identify the corresponding row and column co-ordinates of the 2X2 model to which they apply. General and specific conclusions about flood control in the C&SF project extracted from interviews are listed below. It should be noted that some of the existing problem areas may include sites for reservoirs contained in the alternative plans. Therefore, these cells may show damage potential when in fact none will exist.

E.6.5.2.1 General Conclusions About Flood Control

Most flood control issues can be attributed to four general concerns in the Central and Southern Florida Project area. These concerns are urban encroachment into agricultural areas, little or no buffer zone for urban construction on canals and lakes, inability of discharge in agricultural canals to reach primary systems, and institutional constraints and water management regulation.

E.6.5.2.1.1. Urban Encroachment into Agricultural Areas

Most of the Lower East Coast (LEC) canal systems were designed in the 1960's. Areas that were urbanized or projected to be urbanized at the time of the study were designed at Standard Project Flood (SPF) capacity. Others that were thought to remain primarily agricultural were designed at 30% of SPF or approximately a 10 year storm. Since the 1960's the urbanization of the western portion of the LEC basins, particularly "Area B" in Miami, have lowered the design degree of flood protection, particularly in the western parts of the basins. Increased runoff due to urbanization in the west basin coupled with the lag times involved waiting for the eastern basin to drain has reduced protection in the western areas. This is the case in "Area B" and the Canal 7 basins. In addition, S-97 can no longer pass the design discharge simply because of unexpected urbanization in the St. Lucie Area.

E.6.5.2.1.2. Little or No Buffer Zone for Urban Construction on Canals and Lakes

Eastern basin urban flooding problems that have occurred (C-9 for example) are believed to be the result of urban development encroaching within the right of way of the channels. In addition, development on Lake Istokpoga presents a flooding problem since the development is so close to the lake that there is little effective room for lake regulation.

E.6.5.2.1.3. Inability of Discharge in Agricultural Canals to Reach Primary Systems

Primary flooding within a mile or two of the Bolles and Cross Canal is primarily due to inadequate conveyance and the failure of the canal bank. In addition, subsidence of the land surface has severely affected the ability to pump overland flow to the canals.

E.6.5.2.1.4. Institutional Constraints and Water Management Regulation

The preferred method of drainage in the EAA is to convey water through the North New River and Miami Canals to the Water Conservation Areas. However, actual discharge must be limited in order not to externalize flood problems in adjacent basins. Additional drainage by backpumping to Lake Okeechobee via S-2 and S-3 must be in compliance with the Interim Action Plan[1] for Lake Okeechobee.

[1] In 1979, the Department of Environmental Regulation limited the use of S-2 and S-3 pumping stations to protect the health of Lake Okeechobee. The goal was to pump as little runoff as possible into the Lake, while preserving the capability of major pumps for use in an emergency. The Lake Okeechobee Operating Permit was issued to the SFWMD which defined an objective process for deciding whether or not to pump, based on a number of factors related to how the pumps were operated in the 1970's. The rules governing the operation of these pumps, as stated in the permit, comprise the Interim Action Plan (IAP). The point system used to regulate usage of the pumps can be found on pages 24 and 25 of technical reference 21, listed in Table 6.5.2-1.

E.6.5.2.2 Specific Conclusions About Flood Control

The following information is listed by specific area in the applicable county. The affected areas pertain to row and column designations of the 2X2 grid cell overlay used by the SFWMM. The grid cell designations of the affected areas are shown in Plates 1 through 8 at the end of the chapter.

E.6.5.2.2.1. Miami-Dade County - Area B (Pennsuco/Lake Belt Area) Affected Area (R18-19,C27-28), (R20-24,C27-31), (R25,C27-32), (R26,C27-31), (R27,C27-30), (R28,C28) – Plate 1

There is significant flooding potential in West Miami, Area B, when moderate to high rainfall occurs due to low topographic elevations in the area. The problem is pronounced west of the Palmetto Expressway in Area B where there is much residential development. When the area west of West Miami was undeveloped, storm runoff from the developed eastern area was discharged before the storm runoff from the west reached the primary canals. Since the western area has now been highly urbanized, the western basin must wait for the eastern basin to drain. Observations indicate that flooding occurs more often from long durations of rainfall since these storms create larger volumes of water and it physically takes longer to drain the area. Even when structures are fully open, it takes many days for the groundwater to reach the canal and recede. As stated earlier, seepage problems at L-30 also affect the flood prone nature of Area B.

E.6.5.2.2.2. Miami-Dade County - C-4 (Tamiami Canal) Affected Areas (R22,C30), (R20,C30-31) – Plate 1

During the 1995 storm season, some of the most severe flooding occurred in the western C-4 basin. Three day rainfall peaks exceeded the 100 year rainfall event. Sweetwater (R22,C30) is situated in Area B in the general area of the Pennsuco/Lake Belt Area. Sweetwater is an area where drainage capacity is very limited and was the most heavily impacted during the 1995 storm season. Sweetwater is located at the intersection of the Florida Turnpike and US41 on the northeast corner across the street from Florida International University (FIU). A water elevation of 5.5 feet will cause flooding in the area east of SW 117th Avenue.

Another problem area includes the most western portion of the C-4 basin in Area B and the portion of the C-2 basin north of Sunset Drive (R20,C30-31). In addition to the localized runoff problems in Area B, seepage from L-30 aggravates the flooding problem.

C-4 has been designated as a critical project area with a primary purpose to restore the Pennsuco area. Additional structures proposed on C-4 to maintain higher elevations in the canal may create a flooding problem in the Pennsuco/Lake Belt Area.

E.6.5.2.2.3. Miami-Dade County - S-333 Affected Area (R22,C23-24) – Plate 1

Recommendations for future high water control discussed in 1994-1995 SFWMD publications indicated that better utilization of S-333 was necessary to reduce current operational flow limitation out of WCA-3A. This utilization is limited due to the fact that discharges from S-12A and S-12B have been limited to preserve Cape Sable Sparrow habitat. Therefore, S-12C and S-12D are the only structures which can fully discharge into the Slough. These limitations can compound problems on C-4.

Improvements to Tiger Tail Indian village North of US 41 and flooding mitigation for the East Everglades area are already in progress as a part of the Modified Water Deliveries to Everglades National Park. (R22,C23-24) This area will continue to be monitored in this evaluation.

E.6.5.2.2.4. Miami-Dade County - Miccosukee lands at C-4 Affected Area (R22,C15-17), (R22,C26-27) – Plates 1-2

In 1994 there were storm impacts on Miccosukee lands adjacent to Tamiami trail. The Miccosukee ownership is approximately 500 feet wide and about 5 miles long located south of US-41 at S-12B extending 5 miles west to approximately S-343A. (R22,C15-17). No additional problems are anticipated in the area since additional flood protection has already provided. However, the area between S-12B and L-28 could be susceptible to greater risk with greater discharges into Lostman's Slough. The tribe owns a casino within the triangle at S-335, S-336, and G-119 at (R22,C26-27). Additional development including gas stations and a prison are believed to also be in the area. The area used to be a wetland.

E.6.5.2.2.5. Miami-Dade County - C-7 (Little River Canal) Affected Area (R26-27,C32-33) – Plate 1

Tropical Storm Allison and the flood event of June 18-26, 1995, created some minor flooding problems in the western C-7 basin. Most of the development in the western end is high density residential development with low topographic elevations. The original project design for this channel was 75% of Standard Project Flood (SPF) with the secondary canals in place. This equates to approximately 10 year protection (R26-27,C32-33).

E.6.5.2.2.6. Miami-Dade County - C-111, Affected Area (R10,C25-26), (R11,C25-27), (R12-13,C25-26), (R14-15,C25), (R16,C26) – Plates 1 and 3

Events during the 1994 storm season affected this area. Since initial project construction in the 1960's, damage susceptibility has increased due to the increased value of crops and increased agricultural production which has taken place in the floodplain. Increased agricultural production has occurred since the system has been operated at lower water levels than originally authorized. Two forms of this increase in production are evident. First, highly damage susceptible vegetable crops are being planted earlier in the year, before the actual start of the winter dry season. Second, the amount of fruit tree crops and general horticultural activity have increased in the flood plain. Since these trees have longer root zones than other field crops, they are more susceptible to high water tables and to flooding. The purpose of the General Reevaluation Report for C-111, completed in 1994, was to formulate a plan of improvement that would restore more natural hydroperiods to Taylor Slough in Everglades National Park and maintain the flood protection provided by the existing project. Although stages in C-111 would be reduced when compared to the existing design stages shown in the 1961 report, they would be higher than the current regulation to accommodate increased deliveries to the Everglades National Park. However, higher stages during the winter months can adversely affect truck crops, and root zones of fruit trees can be affected year around. (R16,C26) (R14-15,C25).

E.6.5.2.2.7. Miami-Dade County - L-31N and 8.5 Square Mile Area, Affected Area: (R17-18,C25-26), (R19,C26) – Plate 1

The 8.5 square mile area is located west of L-31N north of the Rocky Glades Area. Flood mitigation for this area was formulated as part of the Modified Water Deliveries to Everglades National ParkThe SFWMD is planning to purchase this area. In 1994, flooding impacts northwest of South Miami Heights were in or around the 8.5 square mile area at (R16,C25-26), (R17,C26).

E.6.5.2.2.8. Miami-Dade County - Rocky Glades Area, Affected Area: (R17,C25-26) – Plate 1

The Rocky Glades area is located west of L-31N, south of the 8.5 square mile area. The area has historically been used for truck crops and citrus. The recommended plan for C-111 includes provision for the purchase of this land, and these purchases should take place before restudy alternatives are implemented. The SFWMD may extend leaseback arrangements to the local farmers with the stipulation that SFWMD will have the authority to vary canal stages at any time of the year regardless of the agricultural use of the land. Agriculture may or may not be in place in Rocky Glades when the restudy alternatives are constructed. However, if agriculture is in place, the farmers will farm totally at their own risk.

E.6.5.2.2.9. Dade and Broward County - C-9 (Snake Creek Canal), Affected Areas: (R28-29,C33-34) – Plates 1 and 4

Tropical Storm Allison and the flood event of June 18-26, 1995 created flooding problems for a small section of a low-lying coastal area in the eastern C-9 basin. This area becomes floodprone when tidal effects back up water from the eastern end. This affect is not discussed further in this report since alternative designs will not alleviate or worsen this type of flooding problem.

The western portion of the eastern subbasin is very prone to flooding because of low ground surface elevations relative to the eastern subbasin. Major storms can reverse flow in C-9 from east to west because of rapid runoff into the eastern reaches. Model results produced by the Miami-Dade County Department of Environmental Resources Management (DERM) indicate that under existing conditions, approximately 19 miles of bank along the canal would be overtopped during a 100 year storm event and any increases in stages from project alternatives may significantly increase flood potential in that area. The Stormwater Management Master Plan produced by DERM in September, 1997 suggests the highest ranked potential flood problems areas in the Canal 9 area are north of the canal and in the western end of the eastern C-9 basin in (R28-29,C33-34).

Observation of historical conditions in the Canal 9 basin suggests that peak stages from storms are becoming higher over time. Regulation of flows is becoming more difficult. The reason for implementation of the basin rule is to cut the peaks off the hydrographs to allow for slower and longer discharges. With wet antecedent conditions, it is more difficult to limit discharge. This regulatory issue could become a problem in the future but not at this time. Although the western area is presently urbanizing, the eastern portion design was 100% of SPF at the time of the project report in 1954.

E.6.5.2.2.10. Palm Beach County - C-18 Basin, Affected Area (R60-61,C34) – Plate 5

A Flood Management Study of the C-18 Basin[2] indicates that the western half of the west branch of the basin and the reach upstream of the C-18 weir lack the capacity to pass the 10 year discharge frequency used in the study. The sum of the permitted project runoff rates from all subbasins greatly exceeds the design capacity of the C-18 system.

This basin has had a significant increase in agricultural and urban development since construction. In 1956, the General Design Memorandum

[2] The study is technical reference 12 listed in Table 6.5.2-1.

predicted there would not be any urban development. There now exist 10,000 acres of agriculture and 6,900 acres of urban development in the basin. (R60-61,C84)

E.6.5.2.2.11. Palm Beach County - Indian Trails Water Control District, Affected Area: (R56,C33) – Plate 5

Indian Trails Water Control District was not a participant in the original C-51 construction. Therefore, the flood control system was not designed for additional flows during flood events to be discharged from the Water Control District into C-51. Currently, subject to SFWMD approval, C-51 receives off peak discharges from the M-1 basin of the Indian Trail Improvement District when such discharge can be received without causing flood impacts to the C-51 basin. When S-155A is placed into operation, a Memorandum of Agreement between the SFWMD and the Indian Trail Improvement District will govern discharge from the M-1 basin into C-51.

E.6.5.2.2.12. Palm Beach County – Levee 8 Conveyance, Affected Areas: (R56-57,C30), (R57-58,C29) – Plate 5

Infrequent major storm events cause problems in the L-8 basin. However, it is not uncommon for ponding problems to persist along the L-8 Tie-Back Levee as a result of long duration wet conditions. This is aggravated by the fact that by design, L-8 should discharge to either Lake Okeechobee or WCA-1. During wet years, stages in both of these regional storage areas are generally high and therefore, effective drainage of the L-8 is hampered. Under this scenario, S-5A(E) can be used during off-peak periods just before or immediately after the peak hydrograph stage has occurred in the C-51 canal, but its capacity is limited. S-5A(W) and S-5A are sometimes used when capacity exists. There is significant local pressure to continually operate S-5A(W) and S-5A as though L-8 were part of the S-5A drainage basin.

E.6.5.2.2.13. Palm Beach County - Everglades Agricultural Area--General

The entire Everglades Agricultural Area (EAA) is subject to severe drainage problems as indicated by the storm event of January 15-17, 1991. During that event, maximum rainfall totals were 11”+ , with an average of 6” falling over the entire EAA. Although the event occurred during the dry season, flood effects were more severe since local growers were keeping water levels high in the canals for irrigation purposes.

The EAA and other agricultural areas in South Florida are designed to remove 0.75 inches of rainfall each day. This level of flood protection is less than that normally provided to urban areas. A simple calculation indicates that it would take over nine days to remove a 7-inch rainfall if all project pumps were operating at full capacity. In addition, drainage in the EAA is greatly reduced due to the three following factors:

First, the drainage of the area for agriculture in the early 1900's has allowed the muck soils to oxidize and subside. Soil subsidence has reduced topographic elevations in the EAA by as much as 9 to 10 feet in some areas. As land elevations decrease and the canal elevations remain the same, it becomes increasingly difficult to move overland flow from the agricultural fields into the canals during a storm event.

Second, there are open channel connections to the North New River Canal and the Miami Canal via the Bolles Canal. Basin boundaries between S-5A, S-2, S-6, and S-7 can vary dependent upon the operation of the structures in the S-2, S-3, S-6, S-7, and S-8 basins. The preferred method of drainage is to utilize the North New River and Miami Canals to the Water Conservation Areas. However, actual discharge must be limited in order not to externalize flood problems in adjacent basins. Therefore, channel capacity becomes the limiting factor and the pumps operate at reduced capacity to prevent pump damage. This requires more time than many crops can survive inundation.

Third, the original operating level for the primary pumping stations that discharge through the Miami and North New River Canals to the WCA's was 13 feet MSL. However, the operating level of the pumping stations was later changed to 11 feet due to soil subsidence. The use of lakeshore pumps S-2 and S-3 to backpump into Lake Okeechobee is governed by the Interim Action Plan (IAP). Although operation of these structures is based upon a point system contained in the plan, usually the trigger is still at 13 feet MSL for these structures. The viable need to maintain water quality in Lake Okeechobee via restricted usage of these pumps reduces the Water Management District's flexibility in reducing flood damage in this area.

E.6.5.2.2.14. Palm Beach County - Bolles and Cross Canal (S-2, S-6, S-7, S-8), Affected Area: (R53,C18-22,R52,C18-22, R51,C18-24, R50,C18-25, R49,C18-25.) Plates 5 and 6

The Bolles and Cross Canal drainage area is located in the EAA. During the 1991 event described above, the area was severely flooded. Primary flooding at Bolles and Cross was located within a mile or two of the canal and was due to inadequate conveyance and the failure of the canal bank. The culverts on Bolles and Cross Canal do not effectively move water through the system and probably need to be replaced by bridges. Also, water pumped into the canal from adjacent fields would simply breech the canal and flood elsewhere. In addition, the conditions were aggravated due to the drainage restrictions listed above for the EAA.

The actual floodprone area of Bolles and Cross can vary considerably due to the rainfall distribution, duration of the storm, and how the system is operated.

Much of the area within two miles of the canal is 10.5 feet MSL. Although the remainder of the EAA is probably wet also, topographic elevations are higher than 10.5 feet MSL. Pre-subsidence information indicates the southern area can vary from 12 feet to about 20 feet MSL.

It is believed there is little or no problem in the area west of Miami Canal in S-3 since it is primarily pasture and incurs little or no flooding from Bolles and Cross. Also, the area east of Hillsboro Canal drains into the Ocean Canal and has less effect upon Bolles and Cross. Therefore the area of concern is defined to include the S-2 basin, excluding the area east of the Hillsboro Canal and the S-6 basin where there is permitted agricultural land use excluding the cells R49,C18-19 which are designated to be reservoir sites with project alternatives.

E.6.5.2.2.15. St. Lucie County - C-23, Affected Areas: (R69,C34), (R70,C33) (R72,C25-31) – Plate 7

S-97 was designed as part of C-23 for agricultural discharge. However, the entire area has urbanized, overloading the structure. Currently, S-97 (R72,C31) cannot pass the design discharge without opening the gates past the maximum designed level. During a flooding situation, it is felt the water would pond behind S-97 along C-23 and cover the area from (R72, C25-30). In addition the St. Lucie Settlement is located at South Fork on the St. Lucie River downstream of S-80 at (R69,C34) and (R70,C33). St. Lucie Settlement is an example of urban development building up to the edge of the canal. The area is affected by S-80 discharges and high tide. This area is noted as an area of concern but cannot be evaluated because the area is outside SFWMM grid.

E.6.5.2.2.16. St. Lucie County - C-25--General

C-25 and S-99 were designed to pass thirty percent of the Standard Project Flood, and to meet irrigation delivery requirements for the basin. However, much of the western part of the basin has limited flood protection. The area is on the Water Management Boundary between SFWMD and Upper St. John Water Management District (USJWMD). Landowners in this area rely on on-site retention for flood protection and drainage. The 1995 land use indicates almost all of the western basin is agricultural with some citrus. This area is noted as an area of concern but cannot be evaluated as the area is outside SFWMM grid.

E.6.5.2.2.17. Collier & Hendry County -- S-140 Seminole & Miccosukee Lands, Affected Area Seminole Lands(R40,C15), (R41-42,C9-14), Affected Area Miccosukee Lands (R36-39,C15-16) – Plate 8

Both tribal areas are located in the Big Cypress drainage area. The original flood control project for the area utilizes gravity drainage and was designed at approximately 30 percent of SPF in the early 1960's. The developed land use in the area is for cattle production. The land use was never expected to be intensified beyond its use as unimproved pasture. With this in mind, the capacity of S-140 was designed so that duration of flooding with a 10 year event would never exceed 10 days. This resulting capacity is 7/16 inch per day. This is less than the general agricultural design rate of ¾ inch per day used in much of the C&SF basin.

The Corps of Engineers is involved in a critical project at Big Cypress that will utilize impoundment areas to improve flooding conditions on the western portion of Seminole land. The Seminoles are also working with the Natural Resource Conservation Service (NRCS) to improve flooding conditions on the eastern portion. Several proposals for improving flood conditions on Miccosukee land have been discussed but none have been agreed upon. The affected areas listed include the Seminole and Miccosukee lands currently in agriculture. The Miccosukee lands South of I-75 and in WCA 3 are excluded since these areas are not capable of agricultural use. Seminole lands in Hendry County located in Row 49, Columns 7-13, are not currently in the model and are not evaluated.

E.6.6 EVALUTION OF ALTERNATIVES

E.6.6.1 General Information

This section is devoted to reducing the sensitive areas listed above that have existing flood hazard potential to a list of areas that are affected either favorably or adversely by the C&SF study alternatives. It should be noted that additional areas that do not have existing problems may also be beneficially or adversely affected by alternatives to the extent flood problems may be created or alleviated. The identification of these areas is beyond the scope of this study. Detailed topographic and stage-hydrograph information is required to compute depths of flooding to structures and duration of flooding to agriculture. Due to the regional design of the SFWMM, this information is currently not available. The evaluation of alternatives is conducted primarily using the output of the SFWMM. Numeric model results have been converted by the SFWMD to easily read charts and graphs called “performance indicators” and posted using the software Adobe Acrobat to the internet for public dissemination. The performance indicators used for the flood damage evaluation include average ponding depths, peak stage difference and stage-duration.

It must be emphasized that the SFWMM was not developed as a flood prediction or flood analysis model and is not intended for these purposes. The SFWMM can only be used as a general indicator of flooding risks on a subregional scale. Site-specific inferences about changes in flood risk will require more detailed investigation in subsequent studies.

E.6.6.1.1 Average Ponding Depth Maps

Maps of the SFWMM area grid cells are posted which describe average ponding depths for each alternative and the base conditions (1995 and 2050) during the summer (May) and winter (October). These maps have the advantage of being able to show actual ponding stages for each grid cell in the study area but also have the disadvantage of only showing this average monthly information for the simulation period for the two months. Nevertheless, they will be most useful in flagging situations in which there is a seasonal buildup of water levels through the wet season ending in October. This would indicate a problem in maintaining historical water levels.

E.6.6.1.2 Peak Stage Difference Maps

Maps of the SFWMM area grid cells showing the percentage of years during which the peak stage for an alternative differs from the peak stage for the 1995 or 2050 base by several fixed amounts are available. These maps show spatially where peak stages have either increased or decreased during the 31 year period of simulation possibly indicating areas subject to increased or decreased flood risk. These maps have the advantage of being able to show actual likelihood of impacts during the simulation period regardless of the month the event occurs. However, these maps have the disadvantage of only showing this information for selected target peak stage differences. Flood damage potential to agriculture is primarily a function of the duration of flooding. These maps give no indication of the duration of these stages, or whether the peak stage occurs above or below the ground surface.

E.6.6.1.3 Stage-duration Curves

Stage-duration curves are also available for selected grid cells in the SFWMM area. The advantage of this information is that a continual relationship between exceedence frequency and stage is displayed for the base conditions and each alternative for the 31 year simulation period. This information has the disadvantage of only being available for selected grid cells.

In addition to the performance indicators listed above, interviews with knowledgeable people and notes and memorandums provided by the Alternative Evaluation Team (AET) have been used to help evaluate alternative performance.

E.6.6.2 Evaluation Methodology and Results

E.6.6.2.1 Adversely Affected Areas

Average May and October ponding depths for base and alternative conditions are displayed for selected cells where concern has been identified during the initial stage of the evaluation. This information is shown in Table 6.6.2.1-1. From Table 6.6.2.1-1, four additional tables are created. Tables 6.6.2.1-2, 6.6.2.1-3, 6.6.2.1-4, and 6.6.2.1-5 display increases or decreases in depth expected with alternatives A, B, C, D, and D13R for May and October compared to the 1995 and 2050 base. It should be noted that some of the existing problem areas which show increases in depths may include sites for reservoirs contained in the alternative plans.

Tables ***6.6.2.1-2, 6.6.2.1-3, 6.6.2.1-4***, and ***6.6.2.1-5*** provide useful information for the periods May and October, but contain no additional information about possible adverse conditions that could occur during other months of the year. Therefore, *Table 6.6.2.1-6* and ***Table 6.6.2.1-7*** summarize peak stage differences to determine possible adverse effects. As discussed above, these tables taken from performance indicator maps have the disadvantage of only showing information for selected peak stage difference target elevations. A potential adversely affected area was defined as an area where the peak stage difference was at least 0.25 feet between an alternative the appropriate base condition for more than 0.0% of the years.

A consolidated list of adversely affected areas was then created. This was done by combining Tables 6.6.2.1-2, 6.6.2.1-3, 6.6.2.1-4, 6.6.2.1-5, 6.6.2.1-6 and Table 6.6.2.1-7 together. The information was then resorted by row and column and multiple records for each cell were examined. If any of the records indicated a problem for a given cell, the cell was considered possibly adversely affected. The results of this evaluation are shown in ***Table 6.6.2.1-8***. ***Table 6.6.2.1-9*** displays grid cells that are adversely affected for the Recommended Plan (D13R).

This page is intentionally left blank.

E.6.6.2.2 Beneficially Affected Areas

The evaluation procedure in the preceding paragraphs is designed to show a worst case scenario, i.e., flag any potential adverse effect that might occur with the implementation of project alternatives and identify these areas so that detailed evaluations may be conducted in later studies. The procedure is not designed to make any judgements about the relative flood control merit or lack of merit of any of the alternatives. In addition to adverse effects, alternatives may also produce potentially positive effects. Table 6.6.2.2-1 displays a consolidated list of possible beneficially affected indicator areas**.** This table was constructed in a manner analogous to the preceding tables. ***Tables 6.6.2.1-2, 6.6.2.1-3, 6.6.2.1-4***, and ***6.6.2.1-5*** display decreases in depth expected with alternatives A, B, C, D, and D13R for May and October compared to the 1995 and 2050 base. In addition, peak stage difference maps were used. A potential benefited area was defined as an area where the peak stage difference for an alternative was at least 0.50 feet less than the appropriate base condition for more than 0.0% of the years. Table 6.6.2.2-2 displays grid cells that have potential beneficial effects for the Recommended Plan (D13R). It should be noted that many of the grid cells are duplicated in Table 6.6.2.1-9 and Table 6.6.2.2-2. This is to be expected since there are beneficial and adverse effects that occur under the Recommended Plan to the same areas at different times of the year or in different years of the project life (1995, 2050).

This page is intentionally left blank.

Alternative plans were formulated with the intent of maintaining existing flood control protection. However, incidental increases in flood protection will be realized in areas where additional dynamic storage can be utilized. Additional retention or detention of flood waters during a storm event greater than the design of the system made possible by water supply reservoirs included in alternative plans will produce a greater degree of flood protection in the local area as long as the basin's existing outlet capacity is maintained.

E.6.6.3 Other Concerns

There is well deserved concern about the C-111 basin in South Miami-Dade County. It was noted that for cells R15C26 and R13C25 the results for Alternatives A,B,C,D, and D13R are comparable, and all are above the target by as much as 0.4 feet. In cell R13C25, the alternatives exceeded the two foot root zone almost 50% of the time. However, the 2050 base condition also violates the two foot root zone 40-50% of the time. The depth differences between alternatives and the base conditions for May and October are 0.0-0.1 feet msl., or minimal. However, the peak stage difference maps indicate that annual peak stages in this area are at least 0.25 feet higher for the alternatives than for the base conditions in approximately 7.5% of the years modeled. The alternatives might worsen conditions for an area that will already have water control problems under the future without project condition

E.7 COMMERCIAL NAVIGATION

E.7.1 OVERVIEW

This chapter evaluates the potential impact of the alternative restoration plans on commercial navigation on the Lake Okeechobee Waterway, which includes the lake, the Caloosahatchee River, and the St. Lucie Canal. This waterway has an authorized depth of eight feet and links Stuart on the Atlantic coast with Ft. Myers on the Gulf of Mexico. Commercial vessels, principally barge traffic, use this waterway to save the time and costs of passing around the tip of the Florida peninsula. Water levels – and channel depths – in the Caloosahatchee River and the St. Lucie Canal are regulated by a series of locks and dams on these waterways. However, channel depths in Lake Okeechobee fluctuate with lake stages. Very low lake levels reduce channel depths in the lake below the authorized navigation depth. This depth reduction could prevent passage, delay passage, or induce reductions in vessel loads for some commercial vessels that would pass through this waterway. These navigation impacts could have economic implications for the shippers and for the transportation costs of commodities carried by depth-constrained vessels.

Based on the South Florida Water Management Model (SFWMM) runs conducted for the Restudy, the alternative restoration plans are expected to have varying effects on water levels in Lake Okeechobee. Consequently, the alternative restoration plans will have varying impacts on commercial navigation. In general, the alternative plans are expected to result in a reduction in stage fluctuations on Lake Okeechobee. Of particular interest to commercial navigation is that the alternative plans are expected to reduce the frequency and duration of extremely low lake levels which affect vessel movements.

This analysis of the potential effects of the alternative restoration plans on commercial navigation will focus on the expected differences between the with- and without-project future conditions. The discussion of commercial navigation on the Lake Okeechobee Waterway begins with a physical description of the waterway, followed by a discussion of the operation and use of the waterway, and an evaluation of the potential effects of the alternative restoration plans.

E.7.2 PHYSICAL FEATURES OF THE WATERWAY

The Lake Okeechobee Waterway was completed in 1937 and includes 154 miles of navigation channel and five lock and dam structures. The five locks and dams, which are operated by the Corps of Engineers, are (from east to west): St. Lucie (river mile 15.3) and Port Mayaca (river mile 38.5) on the St. Lucie Canal; and Moore Haven (river mile 78.0), Ortona (river mile 93.6), and W.P. Franklin (river mile 122.0) on the Caloosahatchee River. The Moore Haven and Port Mayaca locks connect the lake with the Caloosahatchee River and St. Lucie Canal, respectively. Using the locks to designate waterway reaches, the channel dimensions of the Lake Okeechobee Waterway at lake elevation 12.56' NGVD are presented in ***Table 7.2-1***. The Lake Okeechobee Waterway has an authorized project depth of eight feet based upon a lake stage of 12.56 feet NGVD. As indicated in this table, there are two routes from Port Mayaca on the lake's eastern shore to Clewiston on the southwestern shore. Route 1, which cuts across the lake, has a deeper channel (8 feet). Route 2, which hugs the eastern shoreline, is known as the rim canal. This route has a shallower channel (6 feet) and is longer than Route 1, but is more sheltered. Lake Okeechobee is famous for its severe wave conditions which can arise rapidly even with modest wind velocities. During inclement weather, the rim canal is the preferred route between Clewiston and Port Mayaca.

TABLE 7.2-1
CHANNEL DIMENSIONS
LAKE OKEECHOBEE WATERWAY

Waterway Reach	Channel Dimensions	Length of Reach
Atlantic Intracoastal to St. Lucie Lock	Outside project limits	15.3 miles
St. Lucie Lock to Port Mayaca Lock	8' x 100'	23.7 miles
Route 1: Port Mayaca Lock to Clewiston (open lake)	8' x 100'	28.5 miles
Route 2: Port Mayaca Lock to Clewiston (rim canal)	6' x 100'	39.5 miles
Clewiston to Moore Haven Lock (rim canal)	8' x 180'	10.5 miles
Moore Haven Lock to Ortona Lock	8' x 90'	15.5 miles
Ortona Lock to W.P. Franklin Lock	8' x 90'	27.9 miles
W.P. Franklin Lock to Gulf Intracoastal	Outside project limits	33.2 miles
	TOTAL	154.4 miles (open lake) 165.4 miles (rim canal)

The depth of the Lake Okeechobee waterway is controlled by managing lake levels - no maintenance dredging is conducted for this waterway. Consequently, lake levels above (or below) 12.56 feet NGVD will result in a corresponding increase (or decrease) in channel depths. So, for example, at a lake level of 11 feet NGVD, the channel depth would be approximately 6.5 feet NGVD in the open lake and 4.5 feet NGVD in the rim canal.

Table 7.2-2 presents the lock dimensions for the five locks and dams on the Lake Okeechobee Waterway. The elevation of the bottom of Lake Okeechobee is approximately equal to sea level. As a result, with a lake elevation at 15.5 feet NGVD, the Caloosahatchee and St. Lucie locks would have a combined lift of approximately 15.5 feet and 14.5 feet, respectively. The difference is explained by the Caloosahatchee locks releasing further inland (upstream) from the coast than the St. Lucie locks. Three of the locks have head differences of several feet. However, two locks have significantly larger head differences. Ortona Lock has a head difference of approximately 8 feet, and St. Lucie typically has lift elevations in excess of 13 feet. The chamber depths of the five locks depend on the lock head. At their lowest operational levels, the chambers would have depths far in excess of the authorized project depths. Therefore, the lock chambers do not constitute depth constraints to waterway traffic under conceivable circumstances.

TABLE 7.2-2
LOCK DIMENSIONS
LAKE OKEECHOBEE WATERWAY

Lock	Dimensions (feet)
St. Lucie	50’ x 250’
Port Mayaca	56’ x 400’
Moore Haven	50’ x 250’
Ortona	50’ x 250’
W.P. Franklin	56’ x 400’

E.7.3 WATERWAY OPERATION

The Caloosahatchee River and the St. Lucie Canal are primary outlets for Lake Okeechobee. They are also critical components of the Lake Okeechobee Waterway. The locks and dams are operated in a manner that supports commercial navigation as well as other project objectives. Each of the locks and dams has a spillway that can be used for regulatory releases. The spillways and the locks release freshwater downstream and eventually into the Gulf of Mexico and the Atlantic Ocean. Releases are carefully controlled to regulate lake levels, maintain adequate depths for navigation in the two outlet waterways, and minimize salinity impacts on the two receiving estuaries.

Water is typically released through the Caloosahatchee River before the St. Lucie Canal for two reasons. First, freshwater releases to the St. Lucie Canal are limited due to greater ecological effects of freshwater releases on the estuary. Second, the water treatment facility for the town of Olga is located in the Caloosahatchee reach between the W.P. Franklin and Ortona locks. The plant is not allowed to discharge chloride-treated effluent to the river if chloride concentrations in the receiving waters are in excess of 250 parts per million (ppm). The three Caloosahatchee locks and dams are typically operated to keep salinity in this river reach low enough to receive the plant effluent. Since the Caloosahatchee River downstream of the W.P. Franklin lock is tidal, this involves a continual release of freshwater from the lake. In addition, the lock operators will occasionally flush the waterway to remove algae and to restore dissolved oxygen levels. In the

St. Lucie Canal, the St. Lucie Lock is the main interface between the lake and the Atlantic Ocean. When the lake level is below 14 feet NGVD, the Port Mayaca Lock is opened, and water levels for the reach from the lake to the St. Lucie lock are controlled by lake levels.

During water shortages, the operation of the Lake Okeechobee Waterway is altered. In all four phases of the SFWMD's Water Shortage Plan, lock operations can be restricted to conserve water in Lake Okeechobee and maintain acceptable salinity concentrations in the estuaries downstream of the locks. The operation of the W.P. Franklin Lock is a particular focus of the plan. Under the Plan, the SFWMD will request the Corps to limit lockages at W.P. Franklin to once every 4 hours if chloride concentrations at the lock exceed 180 ppm and a rainfall event in excess of 1 inch in 24 hours is not predicted in the surface water use basin within the next 48 hours. If these restrictions are insufficient to reach the salinity target at W.P. Franklin, the SFWMD can then request the Corps to restrict lockages to once every 4 hours, two days per week. If these additional measures are insufficient, the SFWMD can ask the Corps to prohibit lockages.

E.7.4 WATERWAY USE

As shown in ***Table 7.4-1***, the Lake Okeechobee Waterway was used to transport 430,000 tons of freight in 1995. This table, which contains statistics from Waterborne Commerce of the United States, 1997, indicates that petroleum products comprise the overwhelming majority of tonnage shipped. Petroleum products included distillate fuel oil, residual fuel oil, and liquid natural gas. As indicated in ***Table 7.4-2***, commercial navigation on this waterway has been relatively stable over the past ten years, with substantial interannual variability.

The locks on the Lake Okeechobee Waterway play critical roles in movements of commercial vessels. The lock operators maintain records of the lock operations, including the general characteristics of vessels passing through the locks. These data are compiled in a national database, the Lock Performance Monitoring System

(LPMS). This database is maintained by the Corps of Engineers Water Resources Support Center in Ft. Belvoir, Virginia.

Data from the LPMS include characteristics of the commerce vessels used on the waterway. ***Table 7.4-3*** summarizes the LPMS vessel profiles for the Lake Okeechobee Waterway locks for 1996. The lock data contains information about recreational boats passing through the locks, as well as commercial traffic.

The number of tows passing through the locks range from 97 to 226 for W.P. Franklin and the St. Lucie locks, respectively. The average number of barges per tow is small, ranging from 1.1 to 1.5 for St. Lucie and Port Mayaca locks, respectively. The light volume of traffic and small tow sizes indicated by the LPMS data indicate that there are minimal delays at the five locks and dams.

Additional data on the commercial vessels using the Lake Okeechobee Waterway is provided in ***Table 7.4-4***, which presents Florida state vessel registrations for the counties surrounding the lake. This table includes commercial and recreational vessels by length class. The vessels in this table are primarily small, recreational craft. However, there are larger commercial vessels as well. There is a small but viable fleet of day/dinner cruise vessels that operate during the tourist season from Pahokee on the eastern shore of the lake, and from Ft. Myers. These vessels have relatively shallow drafts, in the range of four to five feet. The smaller commercial craft may be fishing boats associated with marinas or fish camps on the lake. These operations will rent fishing boats, and also offer guide services. The vessel registration information in Table 7.4-4 must be interpreted with caution for two reasons. First, Palm Beach and Martin Counties are coastal counties with potential vessel registrations for the Lake Okeechobee Waterway and the Atlantic Ocean. Second, the county of registration may not necessarily be the same as the county of operation.

E.7.5 ANTICIPATED EFFECTS OF ALTERNATIVE PLANS

The potential effects of the alternative restoration plans on commercial navigation are based on the anticipated changes in the frequency and duration of low stage events in Lake Okeechobee. As shown in Table 7.5-1, the 31-year SFWMM simulations suggest that in the absence of restoration action (i.e., under without-project future conditions), lake stages are expected to be below 12 feet National Geodetic Vertical Datum (NGVD) for 30% of the time. As indicated in this table, the alternative plans are expected to significantly reduce the percent of time when lake stages are below 12 feet NGVD. The Recommended Plan is expected to have similar performance to Alternative D.

E.7.6 IMPLICATIONS FOR COMMERCIAL NAVIGATION

Economic effects on commercial navigation are defined as the changes in the value of resources required to transport commodities and/or the change in the value of output from these goods and services. Changes in transportation costs may stem from changes in: (1) the vessel fleet used on the waterways, (2) efficiency in the use of existing vessels, (3) transit time, (4) origin-destination patterns, (5) cargo handling, (6) tug assistance, and (7) use of waterborne transportation, rather than competing modes. The national economic development (NED) effects include the costs of resources, impacts on net income, and operating costs.

The statistics on waterborne commerce and vessels on the Lake Okeechobee Waterway were complemented by extensive field research. This research included interviews with: (1) lockmasters of each lock, (2) waterway users, (3) waterway interest groups, and (4) Corps operations personnel involved with the Lake Okeechobee Waterway project. These interviews solicited opinions regarding the potential navigation impacts from changes associated with the alternative restoration plans. In addition, the waterway was traversed as part of this field research to identify the sensitivity of commercial navigation to changes in lake levels. This included taking spot soundings to assess channel conditions and evaluate aids to navigation. The findings of this field research are highlighted below.

E.7.6.1 Commercial Traffic

Based on conversations with representatives of the Florida Inland Navigation District, the current and former presidents of the Lake Okeechobee Waterway Association, and the lockmasters, there are no commercial shipping lines with regularly scheduled traffic through the Lake Okeechobee Waterway. The commercial traffic consists of special barge shipments that are taking advantage of the shortcut across the peninsula, which can save 3 to 5 days of travel. In some cases, deep-draft tugs transfer the tows to shallow-draft tugs for passage through the Lake Okeechobee Waterway.

In the absence of an established fleet of vessels using the waterway, the analysis of commercial navigation must depend on records of the shipments collected as part of the waterborne commerce statistics and the LPMS.

The absence of regular vessel traffic through the Lake Okeechobee Waterway combined with the historic profile of vessel and commodity movements suggests that commercial navigation on this waterway will continue at its current level with the same high year-to-year variability experienced over the last decade. It is not possible to estimate if and how the fleet of commercial vessels using the waterway might change with the alternative restoration plans. However, given the low level of existing commercial usage and the absence of any significant restrictions or delays, very little change (if any) would be expected between with- and without-project conditions.

E.7.6.2 Groundings

Interviews held with the lockmasters and Corps operations personnel suggested that when lake levels are below 14 feet NGVD, the frequency of vessel groundings increases. While the problem is most severe for recreational vessels, commercial traffic is subject to groundings as well. In general, groundings occur when vessels do not stay in the channel. Since most commercial vessels will endeavor to remain in the channel, groundings are less of a problem for them than recreational craft. However, at very low lake levels, the authorized channel depths cannot be maintained. Under these circumstances, the Coast Guard will install temporary markers to keep vessels in deep water within the channels. The Coast Guard will also issue a Notice to Mariners warning commercial and recreational navigators about the reduced channel depths.

Of particular concern are two shoal areas that pose hazards to vessels that have drafts close to the authorized channel depth. During average and high lake levels these shoals are not a threat to commercial navigation, but during low lake stages they can be problematic. In particular, there is a rock shelf on Route 2 near Port Mayaca lock and a rocky reef on Route 1 near Clewiston that are hazardous. At Port Mayaca, the shoal allegedly has only 4.5 feet of clearance at lake level 12.56

feet NGVD, and the Clewiston entrance allegedly has less than 8 feet of clearance at the same lake level.

As lake levels decline, there is less margin for pilot error or adverse weather conditions. If commercial vessels stray outside of the channel for any reason, they can run aground. Rocky Reef on Route 1 near Clewiston is particularly unforgiving of errors. Much of the lake bottom is soft, but running aground at this location could cause severe damage to vessels. For commercial traffic, it can be particularly challenging to stay in the smaller channel during low lake levels due to the wave and wind action for which Lake Okeechobee is famous. The lower lake levels compound problems with waves, since the shallower depths exacerbate wave formation.

If vessels run aground, the Coast Guard at Ft. Pierce is contacted, and a tow from Ft. Meyers is requested. If there is danger to life or property, the Corps project operations office in Clewiston, on the southwestern edge of the lake, will provide assistance. The Corps keeps records of such assistance, but only for the past two years. As a result, information about groundings on the lake is primarily anecdotal.

E.7.6.3 Aids To Navigation

Based upon a detailed inspection of the Lake Okeechobee Waterway, it appears there are some problems with aids to navigation that may pose hazards to commercial and recreation vessels. Route 1 across the lake is particularly problematic in this regard. Specifically, the channel markers appear to be spaced too far apart for safe navigation. In particular, offshore from Clewiston, Route 1 turns sharply northward to pass through Rocky Reef at the "Hole in the Wall." There are three buoys that mark the channel through this turn: one for the approach, one for the pivot point, and one for exit. The problem is that inexperienced mariners might be tempted to cut across the hypotenuse of what is almost a right triangle, moving directly from the approach to the exit buoy. Unfortunately, this would be a path directly over the reef. This path might not be problematic during average or high lake levels, but at low lake levels groundings would result.

In addition, waterway users indicate that in some locations the spacing between waterway buoys exceeds the channel dimensions significantly. Again, during average or high water, this may not be a problem, but during low lake levels, shallow water could be encountered, as evidenced by the Coast Guard's placement of temporary markers.

Finally, the channel marker buoys on Route 1 seem to be spaced too far apart. While compass headings for this route are provided in navigational charts for the lake, visual cues (i.e., confirmation) using the channel markers are not possible at some points along this route, particularly offshore of Port Mayaca.

E.7.6.4 Lockage Restrictions During Water Shortages

Restrictions on lockages during water shortages cause delays to commercial and recreational waterway traffic. Delays are offset to some degree by the opening of the Port Mayaca lock during low lake levels. However, there are economic effects associated with these delays, particularly for commercial traffic. Although the restriction of lockages as a result of water shortages is uncommon, the restrictions are perceived by the lockmasters as unnecessarily rigid. The lockmasters report that lockages have been restricted at the same time water releases over the dam spillways were being conducted to control salinity in the waterways and the estuaries. During normal operations, the locks are operated on demand. The lockmasters acknowledge that lockages should be restricted during water shortages, but they suggest that they be given more flexibility to manage lock operations with open-ended performance measures, such as requirements not-to-exceed a specified number of lockages over a given time period.

E.7.7 ASSESSMENT

Based upon field research and database searches regarding commercial navigation on the Lake Okeechobee Waterway, it can be concluded that the effects of the alternative restoration plans on the NED account would be very small. All of the alternative restoration plans are expected to lead to reductions in the frequency of low lake stages relative to the 2050 without-project condition. However, the economic effects of these improvements for commercial navigation are expected to be small. There are some commercial navigation issues on this waterway, all of which are directly or indirectly related to lake levels. However, it is not possible to quantify the impacts of the alternative restoration plans without extensive research to identify the waterway fleet and commodity flows. In addition, the infrequent and irregular nature of navigation on the waterway raises the question of whether shipments through the waterway could be deferred until lake levels increase, with little ill effect. In addition, those shippers who use this waterway may already have adjusted to the fluctuations in lake levels. Revisions in lock management practices during drought conditions, as suggested by the lock masters, could also reduce the impacts of the alternative restoration plans on commercial traffic. Finally, the combination of the minor difference in the frequency of extreme low lake levels among the alternative schedules and relatively light commercial traffic on the waterway supports the conclusion that the impacts of the alternative restoration plans on commercial navigation will be negligible.

E.8 RECREATION

E.8.1 OVERVIEW

This chapter examines the potential effects of the Restudy's five alternative restoration plans (Alternatives A, B, C, D, and the Recommended Plan) on the value of outdoor recreation in south Florida. Florida residents and domestic and international tourists enjoy the state's numerous recreation amenities. At the state level, residents and tourists participated in over 493 million outdoor recreation user occasions in Florida during 1992 (Florida Department of Environmental Protection, 1994). Tourists accounted for over 250 million of these occasions, or 51% of all outdoor recreation in Florida. In 1996, approximately one half of all air travelers to Florida (12,002,961 of 23,510,157) had destinations in south Florida (Florida Tourism Industry Marketing Corporation, 1997).

Most visitors to Florida come to enjoy the pleasant climate and participate in a wide variety of opportunities for outdoor recreation. In 1996, Florida hosted more than 43 million domestic and international visitors (Florida Tourism Industry Marketing Corporation, 1997). The expenditures of these visitors make tourism Florida's largest industry. Tourism directly employs more than 781,000 persons and generates more than $37 billion in annual taxable spending. Outdoor recreation plays a significant role in this industry. Visitors are attracted to the state's recreation amenities, and most recreation activities require significant participant expenditures for preparation, travel, and participation. Since the state's parks and preserves are popular visitor attractions, tourists account for a significant portion of the approximately five million annual visitors to the Everglades-related recreation areas in south Florida.

Outdoor recreation in Florida includes many different activities. A common way of differentiating outdoor recreation activities is to classify them based as "user-oriented" or "resource-based" activities. User-oriented activities, such as individual and team sports, are not dependent on any natural resource setting and can be located, space permitting, on any open site. These facilities are provided for the convenience of the user. For example, a basketball court can be added to a playground. Resource-based activities, such as hunting and fishing, depend on the existence and quality of supporting natural or historical resources.

Recreation on Florida's coastal beaches provides an excellent illustration of resource-based recreation in the state. In addition to its beaches, south Florida has the tremendous resource-based recreation potential provided by the unique and nationally significant natural resources of the Everglades. These resources include the diverse ecosystems within the Everglades and related ecosystems, such as Lake Okeechobee, Biscayne Bay, and Florida Bay.

The economic value of resource-based recreation is determined by the users' willingness to pay for a recreation occasion. The willingness of current and potential users to pay for resource-based recreation of specific quantity and quality constitutes the demand for that type of recreation. The interaction of demand with the quantity and quality of recreation resources available determines the recreation use or "participation" levels for that resource-based activity. When the quantity or quality of recreation resources is modified by a project, such as the alternative restoration plans, the change in value of resource-based recreation is based on the difference in the willingness of users to pay under the with- and without-project conditions.

The restoration of the Everglades ecosystems could potentially have significant impacts on the value of outdoor recreation in south Florida. The hydrologic changes associated with the Restudy's alternative restoration plans have been designed to improve the structure and function of the Everglades ecosystems. These improvements can be expected to result in increases in the quantity and quality of Everglades-related recreation resources. Many tourists and residents recreate in the natural areas of south Florida. If the alternative restoration plans improve the ecology of the Everglades, the quality of the Everglades-related recreation and/or the number of people who participate in Everglades-related recreation could increase significantly. Consequently, the value of outdoor recreation in south Florida could increase as well.

Estimating the future value of Everglades-related recreation in south Florida is problematic, and anticipating the incremental changes in value associated with Everglades restoration is even more challenging. There are four principal uncertainties which challenge forecasting the future quantity and quality of outdoor recreation under with- and without project conditions. Perhaps the most important uncertainty concerns the timing and character of the ecological changes that are expected to result from the alternative restoration plans. At this time the outcomes of the restoration actions can not be predicted. Consequently, secondary effects, such as associated changes in recreation patterns, can not be accurately anticipated.

A second uncertainty is the marketing of tourism and Everglades-related recreation. If the restored Everglades is used to market tourism and recreation in south Florida, the value of recreation could change dramatically relative to the without-project future conditions.

A third uncertainty is the degree to which recreational facilities and recreational access would be developed as part of a restoration plan. Recreation facilities and access, such as visitor centers, scenic overlooks, nature trails, and roads, can greatly affect participation levels.

Finally, there are a variety of economic factors at the national level which can influence tourist and resident recreation demand. These factors include the health of the national economy, levels of disposable income, and the availability and costs of competing recreation opportunities. As described in the 1994 Florida Statewide Comprehensive Outdoor Recreation Plan (SCORP): "Florida tourism and its economic implications are sensitive to national economic and energy policies. The dynamic nature of the industry causes uncertainty in tourism forecasting, making it difficult to accurately project visitation levels for more than one or two years at a time" (Florida Department of Environmental Protection, 1994). As evidence of the challenges of tourism and recreation forecasting, the Florida Tourism and Industry Marketing Corporation limits its tourism forecasts to three years, and the most recent SCORP (1994) used a six-year forecast horizon (to the year 2000).

This chapter explores the potential effects of the alternative restoration plans on the value of recreation in south Florida. Given the above challenges, it is beyond the scope of this analysis to quantify the value of Everglades-related recreation under the with- and without-project future conditions throughout the 50-year planning period. This chapter, however, identifies the principal Everglades-related recreational resources, anticipates future recreation demand using available information, and assesses the potential changes in the value of Everglades-related recreation that could result from the alternative restoration plans.

As part of this investigation, a series of telephone interviews was conducted with experts on Florida's tourism industry, including: (1) representatives of the Division of Recreation and Parks of the Florida Department of Environmental Protection, (2) tourism professionals at the Florida Tourism Industry Marketing Corporation, the state's recently formed public/private partnership to promote tourism, and (3) academic recreation and tourism specialists at the University of Florida Center for Tourism Research and Development and at Florida State University. In particular, the methodology was discussed with Dr. Stephen Holland, Director of the Center for Tourism at the University of Florida. Dr. Holland was a principal author of the Florida SCORP. He concurred that Everglades restoration could significantly affect recreation patterns in south Florida and that the above uncertainties preclude quantitative estimates of the change in the value of Everglades-related recreation.

This chapter is concerned with outdoor recreation in Florida that is: (1) land-based, (2) resource-based, and (3) Everglades-related. The principal focus of the recreation analysis is on nonconsumptive Everglades-related recreation, particularly wildlife watching. In this chapter, hunting is discussed to a limited degree, since some areas of south Florida support significant levels of hunting. As examples, Big Cypress National Preserve allows big game hunting, primarily white-tailed deer and feral hogs, and Lake Okeechobee supports significant levels of waterfowl hunting. Recreational fishing is discussed in a separate chapter with commercial fishing. The recreation discussions begin with a profile of regional recreation resources.

E.8.2 RECREATION RESOURCES

The SCORP is the best source of information on recreation demand and supply at the state and regional scales. It divides the state into 11 planning regions, each with clusters of counties. As indicated in ***Table 8.2-1***, there are three planning regions which encompass south Florida. The three regions contain 13 counties. The alternative restoration plans are not expected to have recreation-related impacts in all of these counties. In particular, Charlotte, Sarasota, and Indian River would be expected to experience insignificant recreation-related effects. Sarasota and Indian River Counties are not within the SFWMD boundaries which define the study area, but they are part of the relevant SCORP Planning Regions and are therefore mentioned in that context.

TABLE 8.2-1
COUNTIES WITHIN SCORP PLANNING REGIONS
POTENTIALLY AFFECTED BY ALTERNATIVE RESTORATION PLANS

Region	Counties
Region IX	Collier
	Glades
	Hendry
	Lee
	Charlotte
	Sarasota
Region X	Martin
	Palm Beach
	St. Lucie
	Indian River
Region XI	Broward
	Dade
	Monroe

Source: Florida Department of Environmental Protection, 1994.

Within the three SCORP regions are a variety of Federal, state, and local recreation resources. ***Table 8.2-2*** contains selected Federal and state recreation resource areas in south Florida.

There are five principal areas in south Florida that support the majority of Everglades-related recreation: Everglades National Park, Biscayne National Park, Big Cypress National Preserve, Arthur R. Marshall Loxahatchee National Wildlife

Refuge, and Lake Okeechobee. The recreation resources of these five areas are described briefly below.

TABLE 8.2-2
SELECTED FEDERAL AND STATE RECREATION RESOURCES
C&SF STUDY AREA

	Recreation Area	County
FEDERAL	Everglades National Park	Monroe, Dade, Collier
	Biscayne National Park	Dade
	Big Cypress National Preserve	Collier
	Arthur R. Marshall Loxahatchee National Wildlife Refuge	Palm Beach
	Lake Okeechobee Waterway	Palm Beach, Martin, Hendry, Glades, & Okeechobee
	Florida Panther National Wildlife Refuge	Collier
	Caloosahatchee National Wildlife Refuge 1/	Lee
STATE	John Pennekamp Coral Reef State Park	Monroe
	Water Conservation Areas 2A and 3A	Broward & Palm Beach
	Rotenberger Wildlife Management Area	Palm Beach
	Holey Land Wildlife Management Area	Palm Beach

1/ J.N. "Ding" Darling NWR

Everglades National Park, created in 1947, occupies over 1.5 million acres in the heart of the Everglades. One-third of this area is covered by water, either the freshwater of the Everglades or the estuarine waters of the park, including Cape Sable, Ten Thousand Islands, and Florida Bay. There are five visitor centers: main entrance (Homestead), Royal Palm, Flamingo, Shark Valley, and Gulf Coast (Everglades City). Park recreation facilities and activities include: ranger-led nature walks, boat tours, hiking trails, tram, overlook towers, fishing, canoe trails, overnight lodging, campgrounds, and backcountry camping. All keys and beaches in Florida Bay are closed to protect wildlife habitat.

Biscayne National Park, established in 1968, lies 21 miles east of Everglades National Park, and occupies 181,500 acres, with over 95 percent of its area covered by water. Visitors must use boats to access most of the park. The park headquarters and visitor center are located at Convoy Point. Popular recreation activities in the park include: glass bottom boat tours, snorkeling, diving, and fishing. There are no campgrounds, but there are a variety of nearby visitor services outside of the park.

Big Cypress National Preserve, which is located on the northern boundary of the Everglades National Park, was established in 1974 to protect the Big Cypress watershed for the park. The preserve occupies over 728,000 acres. Few services are provided to the general public in Big Cypress. Most of the use is by hunters and off-road vehicle enthusiasts. There are two scenic drives through the preserve and a visitor center. The preserve contains 31 miles of the Florida (hiking) Trail and has eight primitive campgrounds.

Loxahatchee National Wildlife Refuge is the only remnant of the northern Everglades. The 146,000-acre refuge is leased from the state by the U.S. Fish and Wildlife Service and is one of three large water conservation areas within the C&SF project. Together, the three areas comprise 850,000 acres of marshlands that are designed and managed for flood protection and water supply. Recreation facilities and activities at the refuge include: a visitor center, nature walks, hiking trails, canoe trails, and fishing.

Lake Okeechobee is one of the largest recreational resources in south Florida. The lake and its associated waterways and shoreline provide a wide variety of land-based and water-based recreation activities for local residents and out-of-state visitors, including: fishing, boating, picnicking, sightseeing, camping, swimming, hunting, air boating, and hiking. The western side of the lake is relatively shallow, with an extensive littoral zone. This area provides important habitat for the lake's popular sport fishery. It also attracts thousands of waterfowl, which lure hunters during the fall migration season.

There are other important (state-managed) lands that are used for recreation (managed by the FGFWFC). These include the Lake Harbor Waterfowl Area and Terrytown (both in the EAA), Rocky Glades WEA, and the Everglades WMA (WCAs 2 and 3), and comprise significant recreational resources, specifically for hunting and fishing (e.g., the L-67 canals, which support fishing tournaments). Further information can be found on this subject in the F&W Coordination Act Report, which is in Section A2 of Annex A. Another recreation resource area that deserves mention is the Florida Keys National Marine Sanctuary.

The SCORP organizes outdoor recreation in Florida into 47 categories that encompass a wide variety of recreation activities including team sports (e.g., basketball and baseball), individual sports (e.g., golf and tennis), hunting, fishing, swimming, and boating. ***Table 8.2-3*** presents descriptive information on the recreation facilities in SCORP Regions IX, X, and XI for 21 recreation categories. These resource-based categories were selected as those which could potentially be affected by the hydrologic changes or ecological changes associated with the alternative restoration plans. This table also includes percentages of the statewide totals for the recreation categories and a summary for the three-region recreation impact area. As indicated in this table, the three-region recreation impact area contains 39 percent of Florida's outdoor recreation acres, 32 percent of the state's hunting acreage, and 40 percent of the state's nature trails.

E.8.3 RECREATION DEMAND

Profiles of existing and future recreation demand in south Florida can be developed by drawing on a variety of information at the national, state, regional, and local levels. The discussions begin with the results of two national surveys on outdoor recreation. These illustrate the participation and expenditures of participants in outdoor recreation activities that could potentially be affected though Everglades restoration. These surveys have relevance for resident and tourist recreation in south Florida.

E.8.3.1 National Recreation Trends

National trends in recreation may help to identify potential or expected changes in the demand for Florida recreation as the result of ecosystem restoration. Two recent national surveys of outdoor recreation have particular relevance for this investigation.

E.8.3.1.1 National Survey of Recreation and the Environment

A National Survey of Recreation and the Environment was conducted in 1994 and 1995 by the Outdoor Recreation Coalition of America. Approximately 17,000 Americans were interviewed in a random sample telephone survey, providing information regarding their participation in 62 recreational activities organized into 13 broad categories.

Table 8.3.1.1-1 presents 1994-1995 participation rates for 26 of the 62 surveyed recreational activities. The activities in this table were selected as those that potentially could be affected by the alternative restoration plans. Of the selected activities, the three most popular groups of activities were outdoor viewing, fitness activities, and outdoor social activities which had participation rates of 76.2 percent, 68.3 percent and 67.8 percent, respectively. Walking was identified as the most popular activity with approximately 134 million participating (66.7 percent of the population). Approximately 124 million recreationists (62.1 percent) enjoy visiting a beach or other waterside and gathering outdoors with family. Sightseeing also had a high level of participation (56.6 percent). Other very popular activities include hiking and backpacking, fishing, boating and camping.

The Outdoor Recreation Coalition conducted a similar national survey of recreation and the environment in 1983-1984. ***Table 8.3.1.1-2*** compares the results of the two surveys. The categories are somewhat different than in ***Table 8.3.1.1-1*** due to differences in the surveys.

TABLE 8.3.1.1-1
PARTICIPATION RATES FOR SELECTED RECREATIONAL ACTIVITIES BY U.S. POPULATION 16 YEARS OR OLDER, 1994-1995

Recreational Activity	Participants (millions)	Percent of U.S. Population
Fitness	136.9	68.3%
Walking	133.7	66.7%
Viewing / Studying	152.6	76.2%
Nature Centers	93.1	46.5%
Visitor Centers	69.4	34.6%
Bird Watching	54.1	27.0%
Wildlife Viewing	62.6	31.3%
Fish Viewing	27.4	13.7%
Other Wildlife Viewing	27.5	13.7%
Sightseeing	113.4	56.6%
Visiting Beach / Waterside	124.4	62.1%
Water-based Nature Study	55.4	27.7%
Camping	52.8	26.4%
Developed Area	41.5	20.7%
Primitive Area	28	14.0%
Hunting	18.6	9.3%
Big Game	14.2	7.1%
Small Game	13	6.5%
Migratory Bird	4.3	2.1%
Fishing	57.8	28.9%
Freshwater	48.8	24.4%
Saltwater	19	9.5%
Warmwater	40.8	20.4%
Anadromous	9.1	4.5%
Catch and release	15.5	7.7%
Boating	58.1	29.0%
Canoeing	14.1	7.0%
Kayaking	2.6	1.3%
Rowing	8.4	4.2%
Outdoor Adventure	73.6	36.7%
Hiking	47.8	23.9%
Off-Road Vehicle Driving	27.9	13.9%
Horseback Riding	14.3	7.1%

Source: Outdoor Recreation Coalition of America, 1997.

This table contains numbers of participants, not participation rates. As indicated in this table, there has been an increase in the number of participants for almost all activities. The 11.4% increase in U.S. population during this period explains some of the change in number of participants. However, some activities are clearly undergoing an increase in participation rates. For example, birdwatching has the largest increase (155 percent) in number of participants from 1984 to 1995. Hiking and backpacking also experienced large increases in participation, 93.5 and 72.7 percent respectively. Walking activity increased 42 percent from 94 million to 134 million participants. Also, since 1984 there has been an increasing interest in specialized outdoor adventure activities such as orienteering, mountain climbing, rock climbing, caving, and special types of wildlife viewing.

In general, the variety of recreational interests in the U.S. appears to be increasing along with recreational participation rates. As future recreation needs and interests develop, it is important to recognize that participation in specific types of recreational activities is often linked to demographic factors such as age and income. For example, participation in activities requiring vigorous exercise is considerably higher for young people than for senior citizens. However, the elderly population has increasing recreation participation because of the growing awareness of the importance of physical fitness. Participation in most activities is low for those with family incomes below $25,000 per year. Interestingly, participation is also low for those with family incomes greater than $100,000 per year. Most outdoor recreational activities appear to be enjoyed largely by the middle class, those with family incomes between $25,000 and $75,000 per year.

E.8.3.1.2 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation

The U.S. Fish and Wildlife Service conducted the National Survey of Fishing, Hunting, and Wildlife-Associated Recreation in 1996. As part of this survey, 22,578 anglers and hunters and 11,759 wildlife watchers were interviewed. The purpose of the survey was to gather information regarding participation and expenditures for wildlife-related activities, including: fishing, hunting, and wildlife watching. National participation and expenditure data for sportsmen and wildlife watchers are presented in ***Table 8.3.1.2-1***. The survey revealed that 77 million Americans aged 16 or older (40 percent of the adult population) enjoyed some form of wildlife-related recreation in 1996 with total expenditures exceeding $101 billion.

TABLE 8.3.1.1-2
TRENDS IN U.S. RECREATION PARTICIPATION, 1982-1994

Recreational Activity	1983-1984 (millions)	1994-1995 (millions)	% Change
U.S. POPULATION	**234,868** (January '84)	**261,575** (January '95)	**11.4%**
Fitness			
Walking	93.6	133.7	42.8%
Viewing Studying			
Bird watching	21.2	54.1	155.2%
Sightseeing	81.3	113.4	39.5%
Camping (overall)	42.4	52.8	24.5%
Camping, developed	30	41.5	38.3%
Camping, primitive	17.7	28	58.2%
Hunting	21.2	18.6	-12.3%
Fishing	60.1	57.8	-3.8%
Boating	49.5	58.1	17.4%

Backpacking	8.8	15.2	72.7%
Off-Road Driving	19.4	27.9	43.8%
Horseback Riding	15.9	14.3	-10.1%

Source: Outdoor Recreation Coalition of America, 1997.

Wildlife watching activities primarily included observing, photographing and feeding wildlife for two types of participants: residential and nonresidential. The residential category included those whose activities occurred within one mile of their home, while the nonresidential group included those who took trips or outings for the primary purpose of observing, photographing, or feeding wildlife. Based on the National Survey of Fishing, Hunting, and Wildlife-Associated Recreation, in 1996 over 62.9 million people in the U.S. participated in wildlife watching. This figure is consistent with the 1995 participation of 62.6 million wildlife watchers reported in the National Survey of Recreation and the Environment.

TABLE 8.3.1.2-1
TOTAL U.S. WILDLIFE WATCHING PARTICIPATION, 1996

Category	Participants	Expenditures
Residential	60.8 million	
Nonresidential	23.7 million	
Total*	**62.9 million**	**$29 billion**

Source: U.S. Fish and Wildlife Service, 1996.
* The sum of residential and nonresidential subcategories does not equal the total due to an overlap in participation.

Table 8.3.1.2-2 presents residential and nonresidential participation in various wildlife-watching activities. Among all wildlife-watching participants, 97 percent (60.8 million) watched wildlife within 1 mile of their home (residential). The most popular residential activities included feeding and observing wildlife, 54.1 and 44.1 million participants, respectively. Approximately 23.7 million people (38 percent of all wildlife-watchers) spent 314 million days in 1996 taking trips for the primary purpose of enjoying wildlife. Of all nonresidential wildlife watchers, 68 percent participated only within their home state, 13 percent traveled only to other states and 19 percent took wildlife watching trips in both their state of residence as well as in other states. Survey results indicated that wildlife-watching trips were evenly distributed among male and female participants. The types of sites visited by nonresidential wildlife watchers included woodlands (77 percent), lakes or streamside (69 percent), open field (63 percent), brush covered (59 percent), wetland marsh or swamp (44 percent), manmade area (39 percent) and oceanside (27 percent). Of the 23.7 million nonresidential participants 22.9 million enjoyed observing wildlife. Observing birds and land mammals was favored by 75 percent of wildlife observers.

Table 8.3.1.2-3 presents a profile of wildlife observed by nonresidential participants by type. Waterfowl and songbirds were among the most popular species watched.

TABLE 8.3.1.2-2
U.S. WILDLIFE-WATCHING ACTIVITY, 1996

Category	Participants (millions)	Average Days / Year (millions)	Average Days / Participant
Total Wildlife Watching*	**62.9 (100%)**		
Residential*	**60.8 (97% of total)**		
Observed Wildlife	44.1		
Photographed Wildlife	16.0		
Fed Wildlife	54.1		
Maintained Plantings/Natural Areas	13.4		
Visited Public Areas	11.0		
Nonresidential*	**23.7 (38% of total)**	**314**	**13.2**
Observed Wildlife	22.9	279	12.2
Photographed Wildlife	12.0	79	6.6
Fed Wildlife	10.0	90	9.0

Source: U.S. Fish and Wildlife Service, 1996.
* The sum of subcategories may not equal the category total due to an overlap in participation.

The National Survey of Fishing, Hunting, and Wildlife-Associated Recreation also contains state-level information on recreation participation and expenditures. In 1996, approximately 3,642,000 of Florida's 11,239,000 residents (32 percent) participated in wildlife-related recreation with the following distribution: 2,840,000 wildlife watching (25 percent of the state population) and 1,988,000 hunting/fishing (18 percent of the state's population). According to the survey, 79 percent of the time spent wildlife watching by Florida residents is spent within the State of Florida.

As indicated in ***Table 8.3.1.2-4***, there were an estimated 1,846,000 participants in wildlife-watching activities in Florida in 1996. Approximately 1,050,000 (57 percent) of these participants were Florida residents and the remainder (796,000 or 43 percent) were from outside the state. Together, the in-state and out-of-state participants spent a total of 14,658,000 days watching wildlife in Florida.

TABLE 8.3.1.2-3
U.S. NONRESIDENTIAL WILDLIFE-WATCHING BY SPECIES, 1996

Category	Participants (millions)	% of Total
Nonresidential	**23.7**	
Birds	17.7	75%
Waterfowl	14.3	
Songbirds	12.9	
Birds of Prey	10.6	
Other Shorebirds	9.5	
Other Birds	6.5	
Land Mammals	17.7	75%
Fish	8.4	35%
Marine Mammals	3.5	15%
Other	11.5	49%

Source: U.S. Fish and Wildlife Service, 1996.

Table 8.3.1.2-5 presents estimated expenditures associated with wildlife watching in Florida during 1996. As indicated in this table, in-state and out-of-state participants spent over $1.6 billion in 1996 on wildlife watching. This includes trip-related expenditures and equipment expenditures. Wildlife watching equipment includes binoculars, film, bird food, and special clothing. Auxiliary equipment expenditures accounted for items such as tents and backpacking equipment. Other expenditures include magazines and books, membership dues and contributions, land leasing and ownership, and plantings.

TABLE 8.3.1.2-4
PARTICIPANTS IN WILDLIFE-RELATED RECREATION IN FLORIDA, 1996

Participant	Residents	% of Total	Non-residents	% of Total	Total
Anglers	1,878,000	(66%)	986,000	(34%)	2,864,000
Hunters	170,000	(92%)	14,000	(8%)	184,000
Wildlife Watchers	1,050,000	(57%)	796,000	(43%)	1,846,000

E.8.3.2 State Recreation Trends

The Florida SCORP supplements the results of the two national recreation surveys described above with estimates of current and future recreation demand at the state and regional scales. Recreation demands were developed for the SCORP through surveys of residents and tourists. The recreation participation information obtained from the 1992-1993 surveys was extrapolated to total number of 1992 Florida residents (13,412,190) and tourists (36,611,280). Participation in outdoor recreation activities is expressed in terms of user-occasions, which occur each time an individual participates in a single outdoor recreation activity. The number of user-occasions was calculated for each planning region as well as the entire state by type of activity. Demand was estimated for 1995 and 2000 by applying the per capita participation rates to population projections.

Table 8.3.2-1 presents 1992 state-wide resident and tourist demand in Florida for selected outdoor recreation activities. The activities were chosen on the basis of their potential for being affected by the alternative restoration plans. As indicated in this table, over 45 million residents and tourists participated in these activities in 1992. Hiking, recreational vehicle (RV) camping, and nature study were popular with residents and tourists. With the exception of RV camping, participation by residents outnumbered tourist participation.

TABLE 8.3.2-1
DEMAND FOR SELECTED RECREATION ACTIVITIES IN FLORIDA
USER-OCCASIONS (thousands), 1992

Activity	Resident	Tourist	Resident & Tourist	% of Total
Hunting	1,656	34	1,690	4%
RV Camping	2,992	5,659	8,651	19%

Table 8.3.2-2 presents participation rates for the same set of recreation activities during 1985 and 1992. In general, residents have higher participation rates than tourists, and participation rates for both groups have declined from 1985 to 1992.

TABLE 8.3.2-2

Tables 8.3.2-3 and ***Table 8.3.2-4*** present age and income characteristics of resident and tourist participants in the same set of recreation activities as in the preceding tables. For residents and tourists, the 25-44 year age group comprised most of the participants in the selected recreation activities. Regarding income characteristics, the middle incomes in general had higher participation rates than the highest income category, and upper income tourist participants in general had higher participation relative to resident participants with similar incomes.

Tables 8.3.2-5, 8.3.2-6, and ***8.3.2-7*** present 1992 and projected 2000 demands for the selected recreation activities in SCORP Planning Regions IX, X, and XI, respectively. These tables include user-occasions as well as facility/resource needs. As part of the without-project conditions, all of the regions are expected to have significant increases in demands for the selected recreation activities with a commensurate need to increase development of the regions' recreation resources and facilities.

E.8.3.3 State Tourism Trends

As described in the SCORP, 43 million domestic and international visitors to Florida per year comprise a significant portion of the overall demand for outdoor recreation resources in Florida. Their participation in resource-based recreation and their relatively high incomes (compared to resident recreationists) make tourists a significant component of Everglades-related recreation in south Florida. Additional insight to the links between tourists and outdoor recreation in south Florida is provided by the 1997 Florida Visitor Study prepared by Florida Tourism Industry Marketing Corporation. The findings of this study are based on interviews with Florida visitors conducted at major entry points to the state (airports and interstate highways). Some of the information developed by the visitor survey applies to the state as a whole; other aspects of the study have direct relevance for Everglades-related recreation in south Florida.

Table 8.3.3-1 contains visitation data for Florida for 1995 and 1996, including travel mode. As indicated in this table, of the 43 million visitors to Florida in 1996, approximately 23.5 million (55 percent) arrived by air travel, and the remaining 19.5 million (45 percent) arrived by automobile. Tourism increased by 4.2 percent between 1995 and 1996 with a significant increase in air travel and a small decrease in automobile travel.

TABLE 8.3.3-1
NUMBER OF FLORIDA VISITORS
1995, 1996

Travel Mode	1995	1996	% of 1996 Total	% Change (1995-1996)
Air Visitors	21,518,096	23,510,157	54.7%	+9.3%
Auto Visitors	19,764,218	19,491,583	45.3%	-1.4%
Total	**41,282,314**	**43,001,740**	**100%**	**+4.2%**

Source: Florida Tourism Industry Marketing Corporation, 1997.

The top ten states of residence of the visitors are presented in ***Table 8.3.3-2*** for air and auto visitors. The top ten states account for the origins of 58 percent of Florida air visitors and 60 percent of auto visitors. As expected, the auto visitors originate in more proximal states than air visitors.

TABLE 8.3.3-2
ORIGINS OF FLORIDA VISITORS
1996

Air Visitors	%	Auto Visitors	%
New York	11.5%	Georgia	17.6%
California	6.2%	Ohio	6%
Ohio	6%	Tennessee	5.5%
Texas	5.7%	North Carolina	5.1%
New Jersey	5.6%	Michigan	4.6%
Illinois	5.3%	South Carolina	4.3%
Pennsylvania	5.1%	Illinois	4.3%
Georgia	4.4%	Alabama	4.2%
Massachusetts	4.1%	Ontario	4.2%
Michigan	4.1%	Pennsylvania	3.8%
Total	**58.0%**		**59.6%**

Source: Florida Tourism Industry Marketing Corporation, 1997.

The visitor survey asked tourists about their county destination. Many of the visitors had destinations in south Florida. For air visitors, Miami-Dade County is the most popular county with over 17 percent of Florida air visitors bound for this destination. Broward County is third with over 15 percent, and Palm Beach County is fourth with over 9 percent. Lee County accounts for 4.6 percent of the destinations, and Monroe is the destination of over 4 percent of air visitors. Together, these south Florida counties comprise 48% of the county destinations for Florida air travelers.

For auto visitors, Disney World (in Orange and Osceola counties) is the premier destination. In south Florida, Broward County is the destination of 4.1 percent of auto visitors, and Palm Beach County is the destination of 4.0 percent.

Many visitors to Florida come for a vacation (air visitors – 35 percent; auto visitors – 58 percent). For air travelers, business is second, accounting for 30 percent of visits, followed by visiting friends/relatives with 28.3 percent. For auto travelers, visiting friends/relatives is second, accounting for 31.2 percent of auto visitors, followed by business visits which account for only 7.9 percent of auto visits. If the numbers of visitors who are vacationing or visiting friends/relatives are combined, an estimated 63.3 percent of air travelers and 89.2 percent of auto travelers come to Florida for non-business travel.

The visitor survey found that parks and preserves of Florida are a significant attraction to air and auto visitors. For air visitors, parks and preserves are ranked second as an attraction with 7.9 percent (after Walt Disney World's 23.8 percent). This percentage represents those respondents who describe parks and preserves as their premier attraction. For auto visitors, parks and preserves were a less significant attraction with a sixth place ranking and 4.3 percent.

The Florida visitor study ranks the top ten activities enjoyed by air travelers and auto travelers. For air travelers, visitor survey respondents ranked "attractions" (including parks and preserves) sixth with 7.8 percent. For auto travelers, "attractions" were ranked fifth with 8.5%, and fishing ranked eighth with 3.1 percent.

Visitation to Florida varies with the seasons. ***Table 8.3.3-3*** presents 1996 Florida air and auto visitation by month and by quarter. As expected, for air and auto visitors, the greatest visitation occurs during the winter months, and the least visitation takes place during the summer months.

TABLE 8.3.3-3
AIR AND AUTO VISITORS BY MONTH
1996

	Air Visitors per Month	% of Total	Auto Visitors per Month	% of Total

Table 8.3.3-4 contains 1996 estimates of air visitor traffic through south Florida airports. As indicated in this table, over 12 million visitors to Florida passed through a south Florida airport in 1996. These visitors accounted for 51% of all air travelers to Florida in 1996. Miami International Airport accounted for more than 60 percent of the air travel to south Florida.

TABLE 8.3.3-4
AIR VISITOR ESTIMATES FOR SOUTH FLORIDA AIRPORTS, 1996

Airport	Air Visitors	% of Total
Fort Lauderdale	2,178,605	18%
Fort Myers	1,346,315	11%
Miami	7,273,431	61%
West Palm Beach	1,204,610	10%
Total (South Florida)	**12,002,961**	**100%**

Source: Florida Tourism Industry Marketing Corporation, 1997.

Florida also receives significant numbers of international visitors. Canadians lead international visitation with 1,913,200 visitors to Florida in 1996. In addition, in 1995, there were 4,161,526 international visitors to Florida, comprising 20.4 percent of all international U.S. visitation.

The 1996 Florida Visitor Study recognizes the importance of marketing activities in developing and maintaining Florida's tourist industry. In 1997, Florida was ranked sixth among states in marketing expenditures for tourism with an estimated $17 million.

E.8.3.4 Trends at Everglades-Related Recreation Areas

As described above, the five principal recreation areas associated with the Everglades are: the Everglades National Park, Biscayne National Park, Big Cypress National Preserve, Loxahatchee National Wildlife Refuge, and Lake Okeechobee. Recreations demands at these five locations are discussed below.

E.8.3.4.1 Everglades National Park

Table 8.3.4.1-1 presents visitation to the Everglades National Park for the 1989-1996 period. During this eight-year period, visitation has ranged from 1,340,988 in 1991 to 909,363 in 1995 (the year which experienced a Federal government shutdown). During this period, the average annual visitation was 1,040,561. ***Figure 8.3.4.1-1*** illustrates the history of visitation to the park. As indicated in this figure, visitation rose steadily from its creation in 1948 to 1972, when the park received 1.8 million visitors. Visitation to the park fell through the mid-1980s and rebounded into the early 1990s. National and international economic and recreation trends underlie some of these changes. The impacts of the decline in the ecological condition of the park on park visitation is not known at this time.

TABLE 8.3.4.1-1
EVERGLADES NATIONAL PARK VISITORS
1989-1996

Year	Visits
1989	979,261
1990	1,002,109
1991	1,340,988
1992	1,064,357
1993	961,643
1994	981,944
1995	909,363
1996	984,825

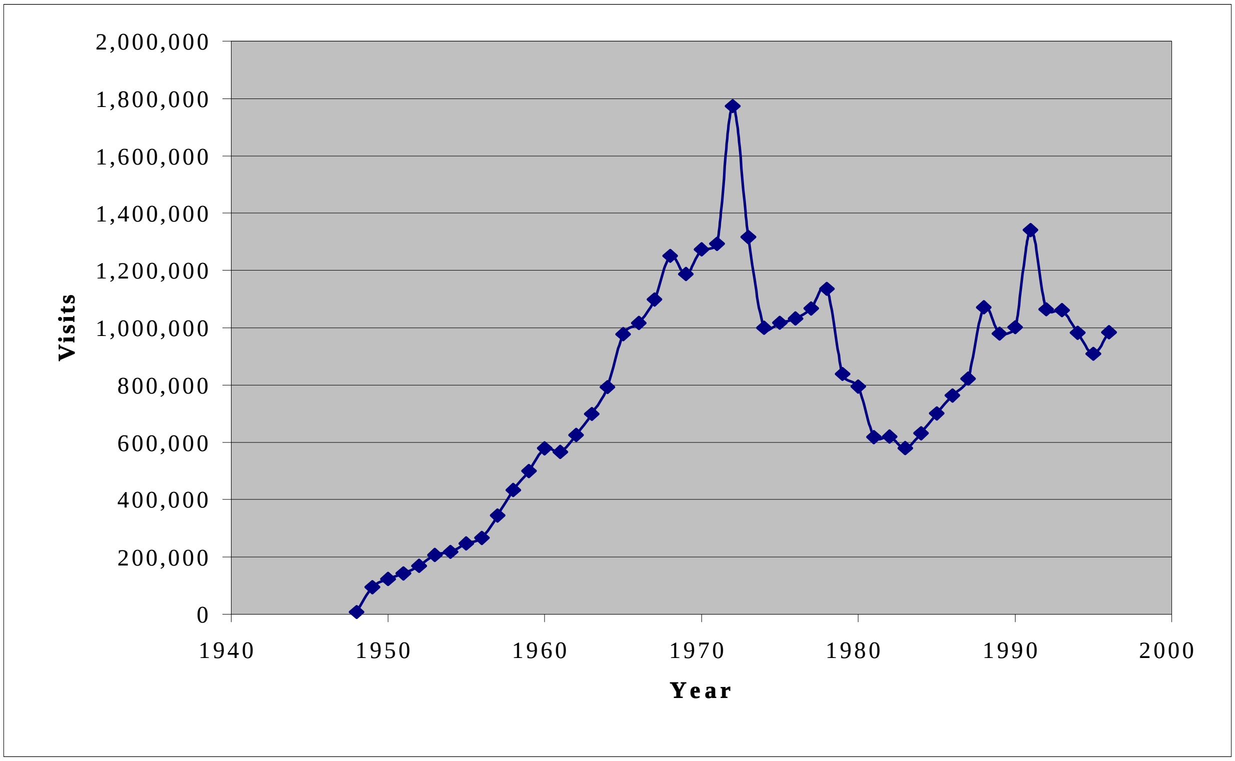

FIGURE 8.3.4.1-1
EVERGLADES NATIONAL PARK VISITATION
1948-1996

The 1996 Everglades National Park Visitor Study provides insights regarding the characteristics of park visitors and their activities while in the park (Littlejohn, 1996). Most of the visitors come in small groups with family (61 percent) and friends (18 percent). Only 12 percent of the visitors indicated that they were part of a guided tour. Many of the visitors to the park were coming for the first time. Of the survey respondents, 60 percent indicated that they had not been to the park within the last five years. The respondents cited many reasons for visiting the park, including:

View wildlife (82 percent),
Experience wilderness (63 percent),
Visit a wetland (59 percent),
Birdwatching (58 percent),
Park is an International Biosphere Reserve (25 percent),
Experience solitude (24 percent),
Fish/power boat (10 percent), and
Canoe/kayak (7 percent).

Most of the park visitors (29 percent) are from Florida. Illinois leads other states with 5 percent, followed by Michigan (4 percent), and New York (4 percent). International visitors are a significant portion (21 percent) of Everglades National Park visitors. Germans constitute 52 percent of the international visitors, followed by British (13 percent) and Canadians (10 percent).

Most of the visitors (75 percent) stay less than one day. Based on the responses of the visitor survey, the average stay in the park is 4.5 hours. Recreation activities during visits include:

Birdwatching (73 percent),
Hike/walk (59 percent),
Ranger-led programs (33 percent),
Picnic (26 percent),
Bicycle (12 percent),
Power boat (11 percent),
Campground (9 percent),
Canoe/kayak (7 percent),
Salt-water fish (7 percent),
Fresh-water fish (6 percent), and
Back-country camping (3 percent)

The visitor survey also queried park visitors about their visit-related expenditures inside and outside the park. Survey responses indicate that 39 percent spent up to $50 in visit-related expenses and that 20 percent spent between

$50 and $100 to visit the park. As indicated in this table, an estimated 76 percent of park visitors spend less than $150 to visit the park.

TABLE 8.3.4.1-2
TOTAL VISITOR EXPENDITURES PER VISIT
EVERGLADES NATIONAL PARK, 1996

Year	Percent of Visitors
>$351	6%
$301-350	1%
$251-300	3%
$200-250	6%
$151-200	7%
$101-150	11%
$51-100	20%
$1-50	39%
No money spent	6%

Source: Littlejohn, 1996.

E.8.3.4.2 Biscayne National Park

Table 8.3.4.2-1 contains visitation information for Biscayne National Park for the 1992 to 1997 period. This information includes visitation to the visitor center, the landside portion of the park, boat tours, visits, and visitor hours. The low visitation to the park in 1993 and 1994 reflect the impact of Hurricane Andrew, which passed directly over the park and devastated park facilities and the nearby City of Homestead.

TABLE 8.3.4.2-1
VISITATION TO BISCAYNE NATIONAL PARK
1995, 1996

	Visitor Center	Outside	Boat Tours	Boat Visitors	Total Visits
1992	n.a.	n.a.	n.a.	n.a.	307,512
1993	16,255	1,753	2,011	n.a.	19,950
1994	17,095	4,674	3,568	n.a.	25,147
1995	18,814	5,605	4,454	559,494	584,519
1996	21,352	4,250	2,894	314,058	338,603
1997	29,192	4,695	3,549	365,586	392,069

Source: Biscayne National Park, 1998.

E.8.3.4.3 Big Cypress National Preserve

Big Cypress National Preserve had 1995 and 1996 visitation levels of 365,500 and 424,920, respectively. Most of these visitors were involved in hunting and off-road vehicle recreation.

E.8.3.4.4 Loxahatchee National Wildlife Refuge

Table 8.3.4.4-1 presents a summary of recreation at Loxahatchee National Wildlife Refuge for the 1992 to 1997 period. As indicated in this table, visitation to the refuge has ranged from 105,581 to 132,549 during this period. Participation levels for the specific refuge recreation activities listed in the table have ranged widely over this five year period.

TABLE 8.3.4.4-1
RECREATION AT LOXAHATCHEE NATIONAL WILDLIFE REFUGE
FY 1992 – FY1997

Year	Visits	Hunting	Fishing	Canoeing
1993	132,549	183	49,586	997
1994	106,264	270	29,215	370
1995	105,581	165	32,270	845
1996	109,032	235	32,185	116
1997	116,300	152	19,633	247

E.8.3.4.5 Lake Okeechobee

Table 8.3.4.5-1 contains information on recreation in the Lake Okeechobee Waterway, which includes the lake, the Caloosahatchee River, and the St. Lucie Canal. The table contents were extracted from the Natural Resource Management System (NRMS), a database that contains visitation information for Corps of Engineers recreation projects. While the visitor hours have varied somewhat over time, the number of visitors to Lake Okeechobee has risen steadily. Sightseeing, fishing, and boating are among the most popular recreational activities on this waterway.

E.8.3.4.6 Aggregate Visitation to Principal Recreation Areas

In 1996, the five principal Everglades-related recreation areas had a total of 5,637,605 visitors. Several simplifying assumptions can be made to estimate the total number of visitors who participate in wildlife watching activities. First, while the proportions of participation in recreation activities in Big Cypress National Preserve are not known, its is assumed that most of the visitors participate in other activities, such as hunting and off-road vehicle recreation. Consequently, visitors to the preserve are not included in the wildlife watching subtotal. Second, the hunting and fishing participants in Lake Okeechobee recreation also were not included. As a result, there were an estimated 5.2 million wildlife watching visitors to the principal Everglades-related recreation areas in south Florida.

E.8.4 POTENTIAL CHANGES IN VALUE OF RECREATION

The information presented in the preceding section provides a profile of recreation at the five principal areas that support Everglades-related recreation. However, in order to estimate the effects of restoration on the value of Everglades-related recreation, the value of a project's recreation resources should be measured in terms of willingness to pay, as specified in Corps guidance (ER 1105-2-100). The best estimates of recreation resource value come from survey-based studies using primary data collected from users and potential users of the recreation resource. For this investigation, the time and budget did not permit the primary data collection required of survey-based methodologies. However, the results of a previous study (Waddington et al., 1994) which estimated the value of non-consumptive recreation in Florida give a perspective on the value of Everglades-related recreation resources. Expenditure data on Everglades-related recreation is also presented to give as complete a picture of the recreation impact of Everglades restoration as existing information would allow.

To estimate the incremental changes in recreation value associated with each of the alternative restoration plans would require an understanding of how a plan's effects on the quantity and quality of recreation resources would modify the demand for that resource. This would require extensive survey-based data collection, as indicated above. Even though the data collection and analysis needed to adequately estimate the recreation effects of the alternative restoration plans are beyond the scope of this report, an analysis of existing data can provide insight to the potential magnitude of the effects of restoration action. This perspective on the economic value of Everglades-related recreation is presented in terms of recreation expenditures and willingness to pay for non-consumptive recreation.

The estimation of expenditures on Everglades-related recreation can be conducted at the regional and local scales. As indicated in ***Table 8.4-1***, the SCORP can be used to estimate expenditures on wildlife-watching recreation in south Florida at the regional scale. The SCORP estimated year 2000 user-occasions for five selected recreation categories used in the SCORP: recreational vehicle camping, tent camping, hiking, horseback riding, nature study, and canoeing. Expenditures per user occasion ($36) are based on the national estimate of expenditures per trip for wildlife watching from the National Survey of Fishing, Hunting, and Wildlife Associated Recreation. Based on this expenditure per user occasion, the year 2000 total expenditures for wildlife watching in the three-region area would be approximately $600 million.

TABLE 8.4-1

A similar analysis can be conducted using the visitation information for the five principal Everglades-related recreation areas. ***Table 8.4-2*** contains the estimated expenditures for wildlife watching in the five areas. The table includes current visitation levels, expenditures per visit, and total expenditures. Expenditures per visit ($64) are based on average trip-related expenditures from the Everglades National Park visitor survey. As described above, visitation to Big Cypress National Preserve was not included in the estimate of wildlife watching visits, and visitation to Lake Okeechobee was adjusted to subtract hunting and fishing activities. Based on these assumptions, the estimated expenditures for wildlife watching at the principal Everglades-related recreation areas in 1996 was approximately $404 million.

TABLE 8.4-2
ESTIMATED EXPENDITURES: EVERGLADES-RELATED WILDLIFE WATCHINGBY RECREATION RESOURCE AREA

	Wildlife-Watching Visits*	Expenditures per Visit**	Total Expenditures
Everglades National Park	984,825	$64	$63,028,800
Biscayne National Park	392,069	$64	$25,092,416
Loxahatchee National Wildlife Refuge	116,300	$64	$7,443,200
Lake Okeechobee	4,820,616	$64	$308,519,424
Total	**6,313,810**	**$64**	**$404,083,840**

* From Park/Refuge visitation data.
** From Littlejohn, 1996.

Expenditures represent the minimum value of the recreation resources, since participants are willing to pay more than they actually expend. Waddington et al. (1994) conducted CVM studies to estimate the willingness to pay of recreationists beyond the willingness revealed in their expenditures. Economists refer to this additional willingness to pay as consumer surplus. For outdoor recreation in Florida, Waddington et al. (1994) estimated the consumer surplus at $46 (in $1997) per user occasion. This estimate of consumer surplus can be applied to Everglades-related recreation at the regional and local scales in a manner similar to the expenditure estimates above. ***Tables 8.4-****3* and ***8.4-4*** present the regional and local estimates of non-consumptive recreation, respectively. The year 2000 regional estimate is $763.5 million, and the local estimate for 1996 is $290.2 million.

Region X (Treasure Coast)	3,749,067	$46	$172,300,183
Region XI (South Florida)	7,551,517	$46	$347,053,749
Total	**16,612,614**	**$46**	**$763,485,002**

* From Florida DEP, 1994.
**From Waddington et al., 1994.

The preceding tables present estimates of the expenditures and consumer surplus for Everglades-related recreation. The estimates contained in the tables provide insight to the value of the Everglades-related recreation resources, but they should not be interpreted as estimates of that value. As described above, this would require survey-based primary research. The regional and local estimates of the expenditures and consumer surplus of Everglades-related wildlife watching are based on secondary sources of information. While the regional and local estimates of expenditures and consumer surplus differ significantly, much of the difference is explained by: (1) the regional approach contains counties that are not in south Florida, (2) the five recreation areas do not represent all of the Everglades-related recreation in the region, and (3) there are four years separating the estimates.

TABLE 8.4-4

The estimates of expenditures and consumer surplus describe existing conditions using available information. The true expenditures and consumer surplus of Everglades-related recreation probably lie somewhere between the regional and local estimates. Regarding future conditions, the differences between the with- and without-project future conditions were not estimated as part of this investigation. As described in the beginning of this chapter, the estimation of the without-project recreation values is problematic, and the assessment of the differences between the with- and without-project conditions are even more challenging. Among the challenges in forecasting future recreation value are difficulties in predicting: (1) the ecosystem changes that will occur as a result of restoration action, (2) differences in marketing activities if restoration occurred, (3) identifying changes in recreation access and facilities as part of the with-project conditions, and (4) broad trends in the economy, tourism, and outdoor recreation.

In addition to these larger issues, there are other area-specific issues that complicate estimating the value of recreation under with- and without-project future conditions. First, the sensitivity of Everglades-related recreation to changes in the ecological condition of the Everglades is uncertain. The quality of a recreation resource is not the only determinant of participation or of value. Second, all of the Everglades-related recreation resources may not be affected by restoration action. For instance, recreation on Lake Okeechobee may experience relatively small effects from restoration, since an important factor affecting lake recreation is that of lake levels, and lake levels are largely determined by the lake's regulation schedule which is assumed to be the same under the with- and without-project conditions. Nevertheless, there are some effects other than lake levels which could impact lake recreation.

More definitive estimates of the value of Everglades-related recreation and the potential economic effects of the alternative restoration plans could be developed through an economic study focusing on the demand for Everglades-related recreation. An original economic study for this purpose would be based on a survey of recreationists to: (1) identify the determinants of demand and (2) estimate the effect of environmental change on the demand for Everglades-related recreation with and without restoration action. The Florida Keys recreation studies conducted by Leeworthy and Wiley (1997,a,b) of the National Oceanic and Atmospheric Administration provide an example of the type of effort that would be required. Available methodologies for this economic study include the Contingent Valuation Method, Conjoint Analysis, and the Travel Cost Method.

Any study estimating the incremental changes in the value of Everglades-related recreation due to the alternative restoration plans would necessarily be conditioned upon multiple assumptions concerning hydrological, ecological, and economic relationships. There are too many uncertainties involved in estimating and differentiating the with- and without-project future conditions to provide a definitive single value of restoration. However, the survey could be structured to query the hypothetical participation and valuation for recreation in the Everglades under various conditions, including ecological conditions, recreation access and facilities, and level of recreation marketing. Survey questions could be constructed to assess the sensitivity of the value of Everglades-related recreation to changes in the quantity and quality of recreation associated with diverse restoration outcomes and recreation features in the alternative restoration plans.

In sum, the Everglades ecosystems support a significant amount of outdoor recreation in south Florida. Currently, there are over six million visitors annually to the Everglades-related parks and preserves and over 16 million annual user occasions of wildlife watching in the region. Estimates of current annual Everglades-related recreation expenditures range from approximately $404 million (for parks and preserves) to $598 million (for the region). The estimated annual consumer surplus for Everglades-related recreation ranges from $290 million (for parks and preserves) to $763 million (for the region). A significant portion of the expenditures come from tourists who in some cases are spending a substantial portion of their disposable incomes in south Florida. It is not possible at this time to anticipate how expenditures and consumer surplus associated with Everglades-related recreation would change if restoration occurred. Given the potential levels of expenditures and consumer surplus in the future, a small percentage increase in the quantity or quality of Everglades-related recreation could represent a large change in recreation value.

E.9 RECREATIONAL AND COMMERCIAL FISHING

E.9.1 OVERVIEW

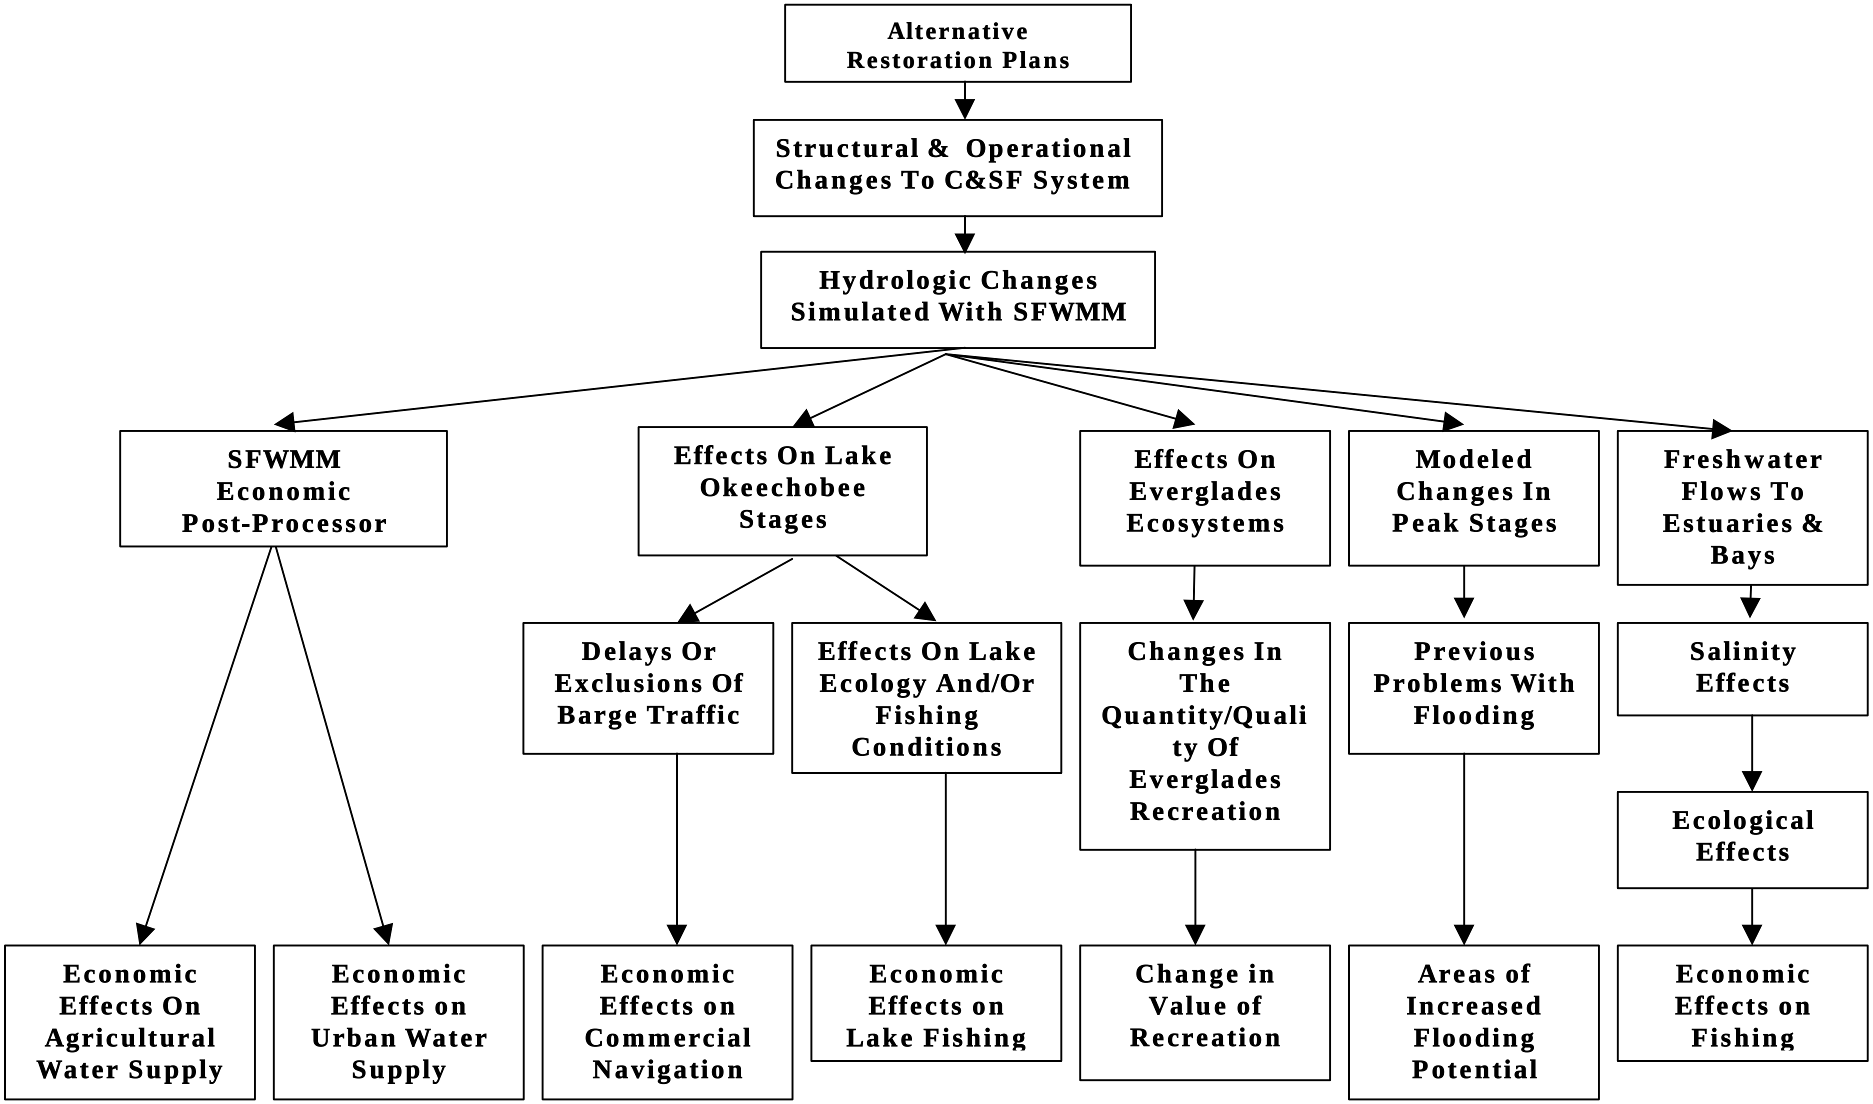
This chapter addresses the likely economic effects of the five alternative restoration plans (Alternatives A, B, C, D, and the Recommended Plan) on commercial and recreational fishing in south Florida. The alternative plans have the potential to affect recreational and commercial fishing throughout south Florida by modifying the hydrologic regime in the region's waterways and estuaries. There are five principal fishing impact zones that would experience the majority of the potential economic effects on fishing in the region: Lake Okeechobee, the Caloosahatchee and St. Lucie estuaries, and Biscayne and Florida Bays.

Both recreational fishing and commercial fishing are discussed in this chapter. Recreational fishing is most often represented by sportsmen who fish from their boats or from the shore; while commercial fishing is generally represented by watermen who earn their living from the sale of the fish they harvest. In some cases, the effects of the alternative restoration plans are evaluated separately for these two groups. In other cases, the distinction between commercial and recreational fishing is less clear and the two are evaluated together. For example, guided sportfishing and commercial headboats occupy intermediate positions between recreational and commercial fishing.

As illustrated in ***Figure 9.1-1***, the linkages between hydrologic changes that are expected to result from the alternative restoration plans and the economic effects on commercial and recreational fishing in the five impact zones differ. Economic effects on commercial fishing are estimated based on a net income approach. Increases or decreases in the net income of commercial fishermen can result from either changes in the size of the catch (i.e., revenues) or from changes in the cost of fishing operations (i.e., expenses). For recreational fishing, economic effects are measured based on changes in both the quality of the fishing experience, as well as changes in the frequency of fishing in a given area (e.g., number of fish caught per trip, number of trips, number of fishermen, or hours fished per trip).

In the case of Lake Okeechobee, the potential effects of the alternative plans on fishing result from changes in the extent or timing of lake elevations (i.e., stages) and changes in water quality. Changes in the frequency of extremely high or low lake stages may impact the lake's commercial and/or recreational fishery by affecting the quantity of fish in the lake, the mix of species, and/or the fishing conditions.

FIGURE 9.1-1
SOURCES OF ECONOMIC EFFECTS



For the St. Lucie and Caloosahatchee estuaries, the alternative plans are expected to change the quantity and timing of water releases from Lake Okeechobee and local basins to the St. Lucie Estuary (Indian River Lagoon north to Port St. Lucie Inlet on the Atlantic coast) and to the Caloosahatchee Estuary (on the Gulf coast). Releases are made to reduce high stages in Lake Okeechobee and to maintain a minimum level of freshwater inputs to the estuaries. Modification of freshwater releases from the lake would yield a sequence of effects on these estuaries, including: (1) changes in salinity levels, (2) consequent ecological effects, and (3) resultant economic impacts on commercial and recreational fishing. In general, these estuaries receive too much freshwater during the wet season and too little freshwater during the dry season. The result is an oscillation in salinity levels in the estuaries that exceeds the natural fluctuations that occurred prior to implementation of the regional water management system.

For Biscayne and Florida bays, the cause-and-effect relationship between hydrologic changes and economic impacts are similar to the Caloosahatchee and St. Lucie estuaries. However, there are also a number of important differences between the bays and estuaries. First, both bays are significantly larger than the St. Lucie and Caloosahatchee estuaries. Second, groundwater inputs to Biscayne and Florida Bays have greater significance than in the two smaller estuaries. Third, freshwater inputs to the bays are generally lower throughout most of the year than had occurred prior to modification of the natural system. Fourth, freshwater inputs to Biscayne and Florida Bays are not characterized by the significant seasonal fluctuations experienced in the St. Lucie and Caloosahatchee estuaries. Fifth, Biscayne and Florida Bays are designated as National Parks and contain fish and wildlife resources of national and international significance. Finally, the bays are at the downstream terminus of the Everglades ecosystem, and the amount and timing of freshwater flows to these bays are less certain than the regulatory releases to the St. Lucie and Caloosahatchee estuaries.

For each of the five fishing impact zones, the level of understanding and availability of data characterizing the cause-and-effect relationship between hydrologic effects of the alternative restoration plans and the associated economic impacts on fishing differ. As a result, the ability to accurately estimate the economic effects on fishing in these areas varies. In general, it is not possible to adequately assign economic values to the anticipated hydrologic and ecological effects of the alternative restoration plans if these precursor effects cannot be accurately quantified.

The economic analysis methodology used in this investigation consists of four components:

1. Quantification of commercial and recreational fishing activities (without-project condition);

2. Identification of the linkages (cause-and-effect relationships) between hydrologic changes, ecological impacts; and economic effects;
3. Quantification of the economic impacts, given current understanding and available data; and,
4. Recognition of the limitations of the analysis and identification of gaps in data or knowledge and future research needs.

Monetary economic impacts are quantified in those instances where adequate hydrologic and ecological information is available to determine the physical impacts of the alternative restoration plans on the fisheries. At a minimum, the hydrologic information generated for the alternative restoration plans has been analyzed to determine the potential magnitude of economic effects. The inability to quantify the potential economic effects on fishing at particular locations does not diminish the significance of the potential impacts on commercial and recreation fishing. In these locations, baseline information on the value of the fisheries is presented to characterize the economic significance of fishing in the local and regional economy. Qualitative analysis is then used to evaluate the relative importance of potential changes; and future research needs and data gaps that can be addressed in subsequent studies are identified. The discussions of the five fishing impact zones begin with Lake Okeechobee.

E.9.2 POTENTIAL EFFECTS ON FISHING IN LAKE OKEECHOBEE

Lake Okeechobee is a broad shallow lake with an area of approximately 730 square miles and an average depth of approximately nine feet. The assessment of potential effects of the alternative restoration plans on commercial and recreational fishing in Lake Okeechobee includes: (1) a profile of the commercial and recreational fisheries on the lake, (2) an evaluation of the potential hydrologic and associated ecological changes brought about by the alternative plans, and (3) an economic assessment of the consequences of these changes on commercial and recreational fishing.

E.9.2.1 Profile of Fishing In Lake Okeechobee

Lake Okeechobee contains an extensive commercial and recreational fishery that supports a number of water-based economic activities, including: commercial fishing, guided sportfishing, and recreational angling. Lake Okeechobee is recognized as supporting one of the best recreational fisheries in the nation. The fishery is extremely large and productive, due an extensive, shallow littoral zone (approximately one-quarter of the lake) that provides abundant habitat for juvenile and adult fish.

The potential effects of the alternative restoration plans on these fisheries are associated with changes in the extent and duration of extreme lake stages (high and low) which can impact this littoral zone. As discussed below, these changes could have short-term and/or long-term impacts on the number of fish, the species mix, and fishing conditions on the lake. The assessment of the potential effects of the alternative plans on the lake's commercial and recreational fisheries begins with a description of the fishery.

E.9.2.1.1 Commercial Fishing

Large scale commercial fishing began in Lake Okeechobee around 1900 with the use of haul seines as the primary gear type, although trotlines, pound nets, and wire traps were also utilized. Catfish were the most commonly sought species by commercial fishermen at that time. Other species such as bluegill, redear sunfish, and black crappie, as well as largemouth bass and mullet were also harvested.

In 1916, the Florida legislature imposed the first regulation on the commercial fishing industry, which included a four-month closed season on haul seines, a maximum haul seine length, and a minimum haul seine mesh. Despite these initial regulatory efforts, commercial catches in Lake Okeechobee waned, due in part to over-fishing, and in part to development activities in the lake's zone of influence. For example, the flood control levee constructed on the southern shore of the lake prevented fish from entering adjacent marshes to spawn. In addition, the emerging sportfishing industry began to push for increased regulation of commercial fishing, claiming that commercial harvesting of gamefish, particularly using haul seines, was detrimental to sportfish populations. As a result, commercial fishing became increasingly regulated throughout the 1950's. Stronger restrictions were placed on both the size of the commercial harvest of gamefish and on the use of various types of commercial fishing gear.

In 1976, the Florida Game and Freshwater Fish Commission (GFWFC) authorized a commercial fishing program with the joint goals of improving lake water quality and restoring the sportfishery. The GFWFC recognized that commercial fish harvests are a practical means to improve the structure of gamefish populations, as well as to remove nutrients (nitrogen and phosphorus) from the lake which had accumulated in the fish. The commercial harvest and sale of freshwater gamefish (except black bass and chain and redfin pickerel) and the use of haul seines and trawls were approved. Initially, 40 haul seine permits and 200 trawl permits were issued. To avoid conflicts with popular sportfishing areas, haul seines and trawls were prohibited from operating within one mile of emergent (shoreline) vegetation.

In 1981, a severe drought resulted in historically low water levels in Lake Okeechobee. The lake's littoral zone was almost entirely drained, forcing fish populations from the shallows into deeper, open water. There was widespread concern among sportfishermen that the commercial fishing industry would over-harvest the dislocated fish populations. This concern induced the GFWFC to temporarily suspend the use of haul seines and trawls for the harvest of gamefish.

In November 1982, the harvest and sale of some gamefish and the operation of 10 haul seines were re-authorized. Trawl permits and the commercial harvest and sale of black crappie were not re-authorized.

Regulation of the commercial fishery has remained unchanged since 1982, except for a 1995 state-wide ban on the commercial harvest of striped mullet. Commercial fishing activity is prohibited on weekends and holidays, but otherwise occurs year-round. The three primary gear types utilized on Lake Okeechobee are haul seines, trot lines, and wire traps. Haul seines are used primarily for bream (bluegill and redear sunfish), although the incidental catch (i.e., catfish, bullhead, shad and gar) must also be kept. Most of the current haul seiners operate out of Clewiston, although one operator is located in Pahokee. Daily haul seine harvests are accepted at four local fish markets. Haul seine fishermen are responsible for filing weekly harvest reports with the GFWFC.

During the course of this investigation, interviews were conducted with haul seiners on Lake Okeechobee to: (1) evaluate the operations and economics of commercial fishing on the lake and (2) determine the sensitivity of commercial fishing to changes in lake levels associated with the alternative regulation schedules. Questions about commercial fishing with trotlines and wire traps were answered by local representatives of the GFWFC at their Okeechobee field office.

The total number of haul seine permits is limited to 10 in order to maintain the sustainability of fish yields. The profitability of the haul seine operations on Lake Okeechobee is indicated by the long waiting list for permits. Although some of the vessels are larger, most of the haul seine operations use vessels with lengths of approximately 35 feet. These vessels generally draw four to five feet of water, depending on the vessel and the weight of the catch in the hold.

Haul seiners prefer low lake levels to high lake levels based on the characteristics of their equipment. The seines are set by driving a metal pole into the lake bottom with one end of the seine attached. The fishing boat then motors away, laying the seine in a large arc. The boat slowly completes the circle as it returns to the pole. Another pole is driven adjacent (approximately one foot distance) to the first. The net is pulled through the space between the poles, slowly closing it around the fish. The fishermen report that deeper waters are problematic for haul seines, because they require larger poles which are more difficult to drive into the lake bottom. Haul seiners also indicated that they do not like to fish in deep waters of the lake, since the nets sink into the muddy bottom. It is possible for haul seines to be used at depths over 20 feet, but some fishermen would need to purchase new nets, and the additional costs are compounded by the physical challenge of using haul seines in deeper water.

Haul seiners prefer lake levels that are in the range of 13 to 14 feet National Geodetic Vertical Datum (NGVD). Lower lake levels constrain their movements around the lake. Higher lake levels make their gear more difficult to use and induce the fish to move into shallow waters that are inaccessible to commercial fishermen.

The haul seiners operate year-round. Haul seine licenses require that they fish at least 120 days per year. Haul seiners apparently do not fish much more frequently than the minimum, due to adverse weather conditions on the lake. If winds are in excess of 15 knots, haul seiners generally do not leave port. Lake Okeechobee is famous for its dangerous wave conditions. With even moderate winds, the long fetches and shallow depth of the lake can produce hazardous wave conditions.

Trotline fishermen using trotlines or wire traps on Lake Okeechobee primarily for catfish. Gear regulations do not restrict the length of trotlines; however, each line is limited to a maximum of 500 hooks. Wire trap designs are restricted to two funnels at one end. Maximum trap dimensions must not exceed 7 feet in length or 32 inches in width. Additionally, the minimum mesh size for wire traps is one inch, and all wire traps must be submerged a minimum of three feet. Fishermen using either wire traps or trotlines on Lake Okeechobee must have a state commercial fishing license. Because commercial fishing licenses are not specific to a particular fishery, the number of trotliners and wire trappers on Lake Okeechobee cannot be determined from license data. However, catch by gear type is recorded for Lake Okeechobee through reports that must be filed by each fish house with the GFWFC. Annual commercial fish harvests by species and gear type from 1986 to 1991 and from 1995-1996 are contained in Table 9.2-1. Data from 1992 through 1994 were unavailable. In the 1995-1996 season, haul seines accounted for 67percent of the total commercial harvest in Lake Okeechobee by weight, followed by trotline (33 percent, and wire traps (>1 percent). Catfish (white and channel) accounted for 49 percent of the total catch by weight, followed by shad (26 percent) and bluegill (10 percent) with the other six species together accounting for the remaining 15 percent.

Fishermen who use trotlines and wire nets prefer high water conditions since catfish are generally found in the deeper waters of Lake Okeechobee (Bull et al., 1995). The catfish utilize crevices, natural cavities, and deeper areas during daylight hours, and emerge at night to feed. In Lake Okeechobee, the open water areas are deeper and more turbid, reducing light penetration and providing better catfish habitat.

Lake Okeechobee's commercial fishing industry includes several different types of fishing operations and landside support activities, such as marinas and fish houses, which purchase the catch from the watermen for wholesale and retail distribution. In his study of the economic effects of commercial fishing on Lake Okeechobee, Bell (1987) estimated that there were approximately 80 trotline fishermen operating on the lake. According to GFWFC, there are only a few fishermen who use wire nets, and they are required by their fishing licenses to have at least five feet of water overhead. They generally prefer water depths around 8 feet.

Bell (1987) estimated that there were a total of 230 jobs associated with commercial fishing in Lake Okeechobee. These included 190 jobs for fishermen using all types of gear and 40 landside jobs in local fish houses. As part of this investigation, several fish houses were interviewed to determine current market prices (wholesale) in order to estimate commercial fishing revenues. The following average market prices were obtained from the fish houses: catfish ($.40/lb.), bream ($.90/lb.), shad ($.25/lb.), and tilapia ($.25/lb.). Based upon these prices the current annual value of the wholesale commercial fishery in terms of revenue to the fishermen is approximately $2.3 million ($1997).

There is a continuing controversy in the Lake Okeechobee region regarding the compatibility of commercial fishing and sportfishing. Some sportfishermen accuse the commercial fishermen of degrading the sportfishery by over-harvesting. GFWFC has conducted a variety of studies that suggest that commercial fishing actually benefits sportfishing by removing non-sportfish species and reducing nutrient levels in the lake that these species have absorbed. In general, the sportfishermen seem skeptical, but the GFWFC maintains that the sportfishery has thrived in recent years despite commercial fish harvesting.

E.9.2.1.2 Recreational Fishing

Fishing on Lake Okeechobee attracts recreational fishermen from all over Florida and various locations around the country. Recreational fishermen use the seven commercial marinas on the lake, which provide a variety of services to boaters and fishermen. In addition, there are approximately one dozen fish camps along the lake that rent fishing boats, offer guide services, and provide lodging and other amenities.

For its national recreation database (Natural Resource Management System), the Corps estimated that in FY 1996 over 6,695,300 visitors recreated on Lake Okeechobee. Of these, an estimated 27% (or 1,807,731 visitors) were involved in fishing. The 1996 National Survey of Fishing, Hunting, and Wildlife-Associated Recreation conducted by the U.S. Fish and Wildlife Service estimates that the national average expenditure per person for a freshwater fishing trip is $371. Assuming that the national average is representative of fishing expenditures at Lake Okeechobee, direct expenditures for fishing on Lake Okeechobee would be approximately $671 million annually.

Source: Florida Game and Freshwater Fish Commission (data from 1991-1994 were unavailable)

Recreational fishermen generally come to Lake Okeechobee to fish for largemouth bass, black crappie, and other bream (bluegill and redear sunfish). A creel (i.e., fish catch) survey of lake fishermen conducted by the GFWFC during the 1990-91 season indicated that largemouth bass and black crappie fisheries are thriving. During the survey period, there was a record high of 151,915 largemouth bass caught with a record low angling effort of 264,764 hours. The resulting success rate was 0.58 bass per hour. The black crappie fishery also exhibited record levels during the survey period with 2,084,749 fish taken over 735,795 hours, with a record angler success rate of 2.79 fish per hour. Field discussions with lake anglers suggest that in recent years, the black bass fishing has declined somewhat, and many bass fishermen have started to fish for crappie. Nonetheless, by all accounts the sportfishery on the lake remains healthy at this time. Black crappie are fished most heavily on the north end of the lake and are fished year round by local residents. Black crappie generally prefer the deep waters and only move into shallow, vegetated areas during spawning season (Bull et al., 1995). The season peaks from December to May with an influx of black crappie anglers. Peak bass season begins in December and lasts through March. Bass are fished with even pressure from the northern, western, and southern regions of the lake. The bream season peaks from March through July. Bream are fished primarily on the western side of the lake.

There are 34 boat launching sites which provide fishermen access to the lake. Ramps were of particular interest in this investigation, since ramp access to the lake could be affected by fluctuations in lake levels that result from the implementation of the alternative restoration plans. Only those facilities on the lake that could be affected by changes in lake levels were evaluated. For example, the ramps and marinas along the Caloosahatchee River were not examined in detail. The water levels in this waterway would not fluctuate with changing lake levels, since stages in the river are controlled by the three Caloosahatchee locks. Under most circumstances, the St. Lucie Canal would also not be affected by changing lake levels. However, when the lake levels fall below 14 feet NGVD, the Port Mayaca Lock is opened and the canal fluctuates with lake levels. For this reason, the recreation facilities on the St. Lucie Canal, as well as boat launching facilities on the lake, were examined in detail.

Site visits were conducted to boat launch ramps, marinas, and fish camps on the Lake Okeechobee Waterway (including the lake, the Caloosahatchee River, and the St. Lucie Canal) to evaluate their sensitivity to lake level fluctuations. At each of the marinas and boat launching ramps, spot soundings were taken at the entrance channels and end of ramps to determine whether use of and access to these facilities could be affected by changes in lake levels. In addition, dockmasters were interviewed to determine the depths of their access channels and boat slips.

Lake levels determine where fishermen can go on the lake. Since the littoral zone occupies approximately 25% of the lake area (primarily on the west side of the lake), access to much of the lake is sensitive to fluctuating lake levels. According to discussions with lake fishermen and GFWFC representatives, access to many fishing locations is not possible when lake levels are extremely low (e.g., below 12 feet NGVD). However, the difficulties faced by boat fishermen during very low lake levels are somewhat offset by increased wading opportunities for shore anglers. As an indicator of the sensitivity of recreation to lake levels, the levels are posted daily on the front pages of local newspapers measured to two decimal places. For example, on 22 November 1997 – the day the boat launch sites were surveyed – the Clewiston News reported that the lake level was 15.24 feet (NGVD).

Some of the boat ramps on Lake Okeechobee would be inoperable at extremely low lake levels (i.e., below 10 feet NGVD). However, the depths of the lake at these extremely low lake stages would probably curtail boating activity before lake access via the ramps became a problem, particularly on the western side of the lake. The ramps at Corps recreation sites along the waterway typically extend from 9’ to 21.5’ NGVD. In addition, these specifications are recommended to state and local governments when they construct or rehabilitate boat ramps on the waterway. Discussions with boaters launching from the ramps on this waterway indicated that two feet of water is required at the bottom of the ramp to launch the small (bass) fishing boats that are typically used on Lake Okeechobee. This sets the effective lower limit for fishing boat access from boat ramps at 11’ NGVD.

The spot soundings of 21 boat ramps on Lake Okeechobee were conducted as part of this study, and some of these boat ramps were found to be sensitive to lake levels. Soundings were taken at the lower end of the ramps. Four of the ramps have terminus depths below 5 feet; nine ramps had terminus depths between 5 and 7.5 feet; and five ramps had depths in excess of 7.5 feet. The lake stage at the time of the soundings was 15.2 feet NGVD. Therefore, some of the ramps would be inoperable at the lowest lake levels (below 10 feet NGVD). However, in general, substitute ramps are available for much of the lake, and the economic effects would be limited to the inconvenience of accessing the lake via the next nearest useable ramp.

E.9.2.2 Potential Economic Effects On Fishing In Lake Okeechobee

As part of the field investigations for this study, interviews with commercial fishermen, fish houses, and the GFWFC were conducted to determine the scope of commercial and recreational fishing on Lake Okeechobee and assess their economic sensitivity to the potential changes in lake levels resulting from the alternative regulation schedules. The economic effects of the alternative restoration plans on these fisheries depend on how the hydrologic changes to the lake stages could impact: (1) the ecology of the lake and the number and mix of fish in the lake and (2) physical access to the fishery.

E.9.2.2.1 Potential Hydrologic and Ecological Effects

Prior to 1900, Lake Okeechobee was clear with a sandy bottom (Furse and Fox, 1994). Lake stages varied with the season as overflow from the lake fed the southward sheetflow into the Everglades. However, construction of the levee system around the lake eliminated lake overflow and facilitated backpumping of nutrient-rich water from the Everglades Agricultural Area. In the last 30 years, rising nutrient levels have degraded water quality in the lake, and the lake has become increasingly eutrophic. More than one-half of the lake bottom is now covered with mud (Furse and Fox, 1994). In addition, periodic increases in lake stages – made possible by the levee system – have diminished the habitat quality of the littoral zone.

Understanding the natural history of the lake is an important first step in evaluating the potential ecological effects of the alternative restoration plans. Under natural conditions, lake stages fluctuated. The variations in lake stages supported a diversity of plant communities in the littoral zone, providing high-quality fish and wildlife habitat. Under any given lake level, fishery effects can be viewed as positive or negative, depending on one's perspective. Low lake stages have both positive and negative effects on fish and wildlife habitat. On the positive side, low lake stages:

- Allow muck to consolidate on the exposed lakebed thereby improving water quality and benthic habitat;
- Permit emergent vegetation to extend further into the lake, cleansing the water column; and, Enable the GFWFC to conduct controlled burning of exotic (i.e., non-native) species such as torpedo grass, hydrilla, and cattails, allowing native plants to recolonize the area.
- Would cause dryouts following which native seeds would be expected to germinate regardless of controlled burning

On the negative side, low lake stages can:

- Reduce access of fishermen to the lake, and
- Damage desirable aquatic vegetation, such as bullrush and eelgrass (although undesirable exotics are also damaged when their habitat is drained).

High lake stages also have mixed effects. On the positive side, high lake stages are desirable since they kill undesirable exotic vegetation, such as hydrilla. On the negative side, desirable aquatic vegetation are also adversely impacted by high lake stages.

The ecological effects of changes in lake stages must be evaluated from both the short-term and long-term perspectives. For example, recreational fishing may suffer in the short term when lake stages are low, since the water is warmer and many gamefish are forced from shallow to deep water. However, longer term benefits to fishing from the drawdown can be realized the following year as fish stocks increase due to habitat improvements. Similarly, high lake stages may increase fishing in the short term by allowing better access to the lake, but the inundation of the littoral zone may have adverse effects on fishing the following year as a result of its diminished function as a fish nursery.

The SFWMD has established a Lake Okeechobee Littoral Zone Technical Group to monitor and assess the ecological condition of the lake's littoral zone, specifically the plant communities and their attributes as fish and wildlife habitat. The Group consists of aquatic scientists from the federal, state, and private sectors. The Group has been evaluating the decline in the habitat quality of the littoral zone as manifested by: (1) loss of habitat for wading birds and waterfowl feeding, (2) decline in spikerush and beakrush communities that serve as nursery areas for young gamefish, (3) reduction in number of willows, which serve as rookery sites for wading birds and endangered snail kites, and (4) increase in torpedo grass and cattails which form dense monotypic stands that preclude foraging by birds and (when inundated) support low dissolved oxygen levels.

Among the causal factors for the ecological decline of the littoral zone are excessive fluctuations in lake stage, including the extent and duration of the fluctuations. From an ecological perspective, Lake Okeechobee lake stages are generally higher than desirable during the wet season (June through August) and generally lower than desirable during the dry season (October through March). While some lake stage fluctuations are desirable for purposes of fish and wildlife habitat, the net positive effects begin to erode when the fluctuations inundate or expose the littoral zone to the point of causing short-term and long-term stress on desirable fish and wildlife habitat.

Table 9.2.2.1-1 presents the simulated effects of the alternative restoration plans on Lake Okeechobee stages. The Recommended Plan is expected to produce effects equivalent to Alternative D. The first hydrologic performance measure, percent of time lake stages fell below 12 feet, indicates that all four alternative plans exceed (i.e., improve upon) the performance of the 2050 without-project (base) future condition. Alternative D has the best performance of the alternatives, and Alternative B has the worst. The second performance measure, number of times lake stage was greater than 17 feet for more than 50 days, showed no difference between the alternative restoration plans and the without-project future condition, except for Alternative B. Alternative B showed a slight increase (i.e., negative effect) of one additional occurrence.

TABLE 9.2.2.1-1
SIMULATED EFFECTS OF ALTERNATIVE RESTORATION PLANS ON LAKE OKEECHOBEE STAGES

PERFORMANCE MEASURE	2050 Base	ALTERNATIVE PLAN			
		A	B	C	D/ Rec Plan
Percent of time lake stage < 12' NGVD	30%	16%	20%	16%	11%
Number of times lake stage > 17' NGVD for > 50 days	2	2	3	2	2

E.9.2.2.2 Commercial Fishing

The NED account registers changes in net income from commercial fishing operations. Net income changes can result from either (1) changes in the size of the catch (net revenues) and/or (2) changes in net operating costs of commercial fishermen. In general, commercial fishing on Lake Okeechobee does not appear to be sensitive to the magnitude of the hydrologic changes (i.e., changes in lake levels) that are expected to result from implementation of the alternative restoration plans. This includes potential ecological effects, which could induce changes in the sizes of fish stocks or fish catch, and physical effects, which could affect access to the commercial fishery.

In terms of the size of fish stocks, the ecological effects of the alternative restoration plans could potentially affect the number of fish and mix of species in Lake Okeechobee. The alternative restoration plans are all expected to improve habitat conditions in the lake's littoral zone by reducing the extent and duration of extreme lake stages relative to the future without-project condition. This would probably translate into an increase in the size of commercial fish stocks. The commercial fishermen interviewed indicated that very high or very low lake levels inundate or drain the littoral zone which is important for fish spawning. The higher water temperatures during low water periods were also cited as adversely impacting spawning.

Despite the positive ecological effects of the restoration plans, it is unlikely that resulting marginal increase in fish stocks will significantly affect the size of the sustainable commercial fish catch. The single greatest determinant of the size of the fishing catch (and net fishery revenues) is the complex series of operational restrictions placed on the fishery by GFWFC to promote a sustainable commercial harvest. These regulations are not expected to change between the with- and without-project conditions. It is unlikely that the GFWFC will allow a significant increase in the commercial harvest following implementation of the restoration plans.

In terms of physical access to the fishery, the operating drafts of commercial fishing vessels on Lake Okeechobee are sufficiently shallow to access commercial stocks throughout the range of lake levels anticipated with the alternative restoration plans. However, there may be some marginal benefits realized by reducing the costs of fishing operations, since fishermen seem to prefer lake levels in the intermediate range and the restoration plans are anticipated to moderate lake stage fluctuations.

Regulation of the fishery by the GFWFC appears to be the most significant determinant of both the size of the commercial catch and the net income of commercial fishermen. While the GFWFC has shown in the past (e.g., 1981) that it will modify the restrictions on the fishery in response to extreme changes in lake levels, it is not anticipated that any similar action would be taken in the foreseeable future. Commercial fishing on the lake currently appears to be at sustainable levels. Therefore it is unlikely that any regulatory changes would be made in response to the modest effects anticipated from implementation of any of the proposed restoration alternatives.

E.9.2.2.3 Recreational Fishing

The alternative restoration plans should have a positive effect on gamefish stocks by modulating the fluctuations in lake stages (relative to the without-project condition) and by improving the habitat quality of the lake's littoral zone. There are also short-term considerations regarding whether the fish are "biting". Some local fisherman report that the quality of the fishing declines significantly when lake levels get low, water temperatures rise, and dissolved oxygen levels fall. Others see little change in the quality of the fishing during low lake stages. Discussions with sportfishermen on Lake Okeechobee yield a variety of opinions regarding the critical threshold when lake levels begin to affect the quality of fishing. In general, this threshold was reported to be approximately 14 feet NGVD.

There could be a small increase in the value of recreational fishing through improved access and increased quality of the fishing experience (larger fish and more catch). These improvements can be expected to cause current fishermen to fish more often and new fishermen to enter the fishery. However, as in the case of commercial fishing, recreational fishing on Lake Okeechobee appears to be relatively insensitive to the minor hydrologic and ecological changes that are expected to accompany the alternative restoration plans.

The relationship between quality of fishing and lake levels has several qualifying factors. First, the timing of low lake levels is important relative to the quality of fishing for particular sportfish. The quality of fishing for particular species varies with the seasons. If low water levels occurred at a time during the year when fishing is not normally good, the effects on fishing would be less, relative to peak fishing periods during the year. A second qualifying factor is that low lake levels do not affect the quality of fishing for all sportfish species.

E.9.2.2.4 Summary of Economic Effects on Fishing in Lake Okeechobee

The alternative restoration plans are expected to have positive effects by moderating the extent and duration of extreme lake stage fluctuations. This could improve the habitat quality of the lake's littoral zone, which provides important habitat for the lake's commercial and recreational fish stocks. The commercial fishery is not expected to benefit significantly from this effect however, since neither the size of the catch nor the cost of the catch are expected to change. The recreational fishery might marginally benefit from the anticipated habitat improvements, but the sportfishery is already quite healthy and therefore relatively insensitive to the magnitude of the expected hydrologic and ecological changes. In terms of physical movement around the lake, the commercial fishermen would be unaffected, but the recreational fishermen might experience some improvement in access to the fishery through the reduction of extremely low lake stages.

E.9.2.2.5 Aquatic Vegetation Control

An issue that is related to commercial and recreational fishing on Lake Okeechobee is the control of exotic plants in and around the lake. The Corps of Engineers and the SFWMD have engaged in a cooperative program to control exotic aquatic and emergent species around the lake. From FY1992 to FY1997 the average expenditures on this program were $784,000 annually.

According to the program managers, it is not possible to estimate the potential economic effects of implementation of the alternative restoration plans on the aquatic plant control program, for several reasons. First, there are multiple species targeted by the aquatic plant control program. High and low lake stages can have counterbalancing positive and negative effects on different exotic species. On a year-to-year basis, the problems with exotic plants depend on a complex interaction of climatic conditions, water temperature, and water levels. When water levels are high, exotic emergent vegetation is inundated and killed. When water levels are low, exotic emergent and aquatic vegetation is exposed and the plants dry and can be cleared using controlled burning. Low lake levels also improve access to the exotic melaleuca trees in the lake for "hack and squirt" control using a combination of cutting and pesticide treatment.

E.9.3 LAKE OKEECHOBEE RELEASES TO ST. LUCIE AND CALOOSAHATCHEE ESTUARIES

Stages in Lake Okeechobee are managed to keep lake levels from being too high at the beginning of the wet season (June) to provide flood and hurricane protection; and to keep levels from dropping during the dry season (November to

May) for water supply purposes. The lake has four principal outlets for discharging inflows received from its tributary waterways: (1) evaporation, which in the south Florida climate accounts for 70% of the lake's water loss, (2) the distributary canals that convey water southward to the LEC and the Everglades, (3) the Atlantic Ocean via the St. Lucie canal, and the (4) the Gulf of Mexico via the Caloosahatchee River. The quantity, quality, and timing of the releases to the St. Lucie and Caloosahatchee estuaries are critical determinants of the diversity and productivity of those ecosystems. Management of the lake and the ecological effects on the estuarine ecosystems resulting from the hydrologic changes induced by the alternative restoration plans are described below. The purpose of this discussion is to aid in interpreting the economic consequences of the alternative restoration plans.

E.9.3.1 Management of Lake Okeechobee

Water levels in Lake Okeechobee are managed through regulatory (flood control) and nonregulatory releases. Regulatory releases are made according to the regulation schedule established by the Corps in conjunction with the SFWMD to ensure that the integrity of the levee system surrounding the lake is not compromised by high water levels. Under the current regulation schedule, the lake level will be dropped by releasing water so that elevations do not exceed 15.65 feet NGVD in late May and 16.75 feet NGVD at the beginning of October.

Nonregulatory releases are made to meet: (1) environmental water supply requirements of the Everglades ecosystem, (2) water supply requirements of the LEC, (3) agricultural irrigation water demands in the LOSA, and (4) environmental needs in the St. Lucie and Caloosahatchee estuaries. Nonregulatory releases from the lake to the two estuaries are made in response to particular circumstances throughout the year. In general, releases are made during low flow periods to provide sufficient freshwater inflows into the estuaries to maintain ecologically desirable salinity levels.

As described in Hall (1992), the regulatory releases from Lake Okeechobee are intended to control high lake stages. The releases are controlled by the regulation schedule, which has management zones that specify outlets and release rates according to the time of year and prevailing lake stage (see Figure 9.3.1-1).

Although the regulatory discharges can have negative effects on the St. Lucie and Caloosahatchee estuaries due to excessive freshwater flows into these ecosystems, the releases are necessary during high lake stages to avoid loss of life and property associated with hurricane-generated rainfall and waves. The current regulation schedule (Run25) provides for pulse releases (Levels I, II, and III) to these estuaries during periods of rising lake stage. The pulse releases are designed to avoid the adverse ecological effects of higher releases over more concentrated periods. Pulse releases mimic natural hydrology following rainfall events. The receiving estuaries are able to absorb the pulses without prolonged salinity or ecological effects. While the pulses are effective for moderate regulatory releases, the prospect or occurrence of prolonged high lake stages can necessitate continuous releases from the lake into the estuaries.

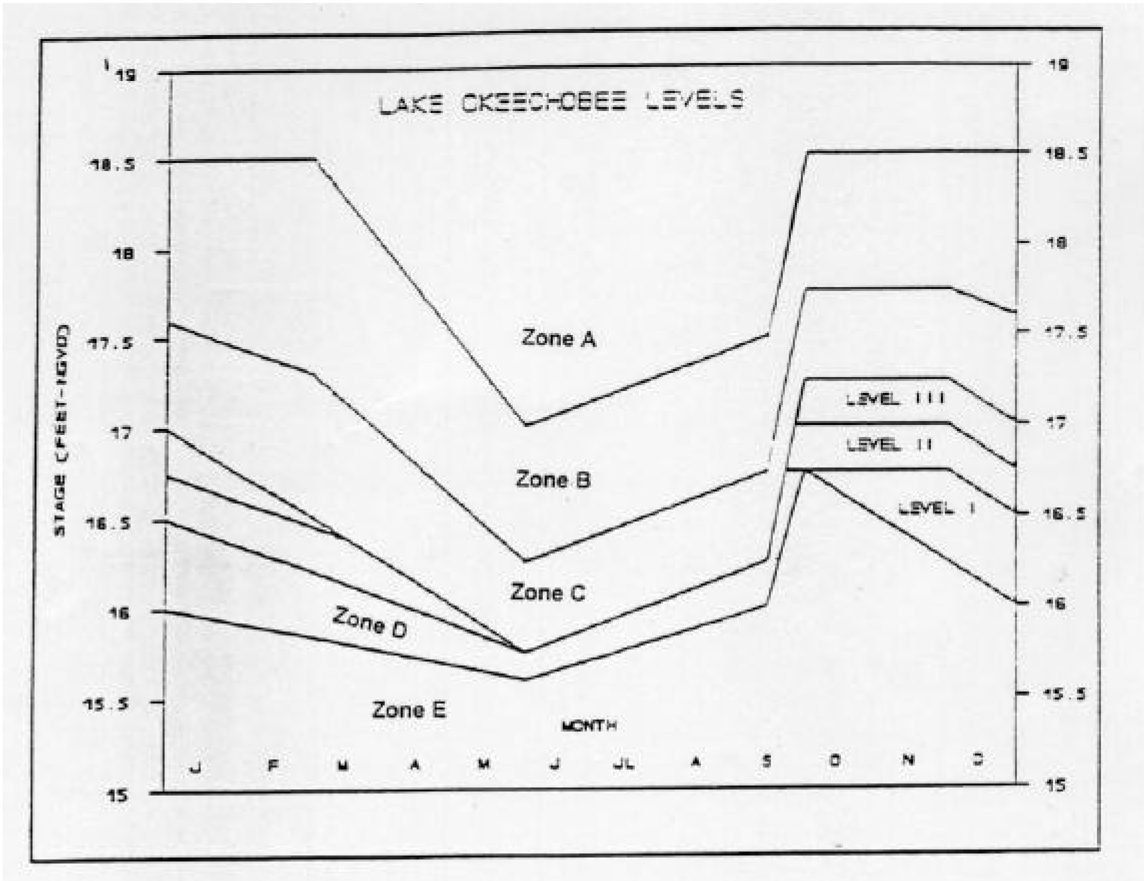
As indicated in ***Figure 9.3.1-1***, the regulatory releases from the lake are directed southward toward the Water Conservation Areas (and the Everglades ecosystem) to the fullest extent possible. When the need for regulatory releases exceeds the receiving capacity of the Water Conservation Areas, releases are made to the two estuaries. In Zone D, maximum non-harmful releases will be made to the St. Lucie and Caloosahatchee estuaries when the lake stage is rising. Based upon field discussions with operators of the water control structures on the Lake Okeechobee Waterway, when moderate releases are required, they will be made first to the Caloosahatchee River and then to the St. Lucie Canal, if necessary. The reason is that the St. Lucie is a much smaller estuary with greater sensitivity to the freshwater releases. When larger releases are required, water must be discharged down both waterways.

E.9.3.2 Effects on Estuarine Ecology

The Caloosahatchee and St. Lucie estuaries are highly productive ecosystems that exist at the interface between freshwater and seawater. The St. Lucie Estuary is a small estuary of approximately 6,000 acres located in Martin and St. Lucie counties. The North and South Forks, which constitute the inner estuary, converge at the City of Stuart where the river widens to one mile after passing beneath the Roosevelt Bridge. Approximately three miles east, the river bends to the south, extending to the southernmost extension of Sewall Point, a spit of land separating the St. Lucie River from the Indian River Lagoon to the east. At this point, both bodies of water empty into the Atlantic Ocean at the St. Lucie Inlet.

The Caloosahatchee Estuary is part of the southern portion of Charlotte Harbor, which includes the estuary, San Carlos Bay, Pine Island Sound, and Matlacha Pass. The estuary extends 29 miles from the W.P. Franklin Lock and Dam near Alva to Shell Point at its mouth in San Carlos Bay. San Carlos Bay, which is bounded by Sanibel Island and Pine Island, is located at the confluence of the river, Pine Island Sound, Matlacha Pass, and the Gulf of Mexico. The freshwater releases into the estuary are controlled by the Franklin Lock and Dam, which also serves as a barrier to salinity and tidal influences upstream.

FIGURE 9.3.1-1
RUN25 REGULATION SCHEDULE



Source: Hall, C.A. Guide for the Management of High Stages of Lake Okeechobee. SFWMD. 1992.

The quantity, timing, and quality of freshwater inputs to estuaries are critical determinants of the structure and function of these ecosystems (Bulger et al., 1990). Freshwater flows provide critical functions and materials for estuaries, including:

- Nutrients for estuarine biota;
- Protection from predation by mature life stages that are intolerant of lower salinities or that are unable to find prey in naturally turbid estuarine waters;
- A range of salinity conditions for a variety of organisms with different requirements for growth and development; and,
- Transportation of many estuarine-dependent larvae.

Relative to natural conditions, the releases from Lake Okeechobee and changes in their watersheds have adversely affected the structure and function of these sensitive ecosystems. In general, the peak flows from the lake to these estuaries are higher than those under natural conditions, and the low flows are lower.

The changes in freshwater inputs to the estuaries have short-term and long-term effects on these ecosystems. The most immediate effect of these changes is the magnification of the natural fluctuations of salinity in these estuaries. Estuarine species evolved under conditions of naturally fluctuating salinity levels, but excessive fluctuations can stress these ecosystems. As described by Bulger et al. (1990), excessive salinity fluctuations can keep estuarine biota in constant flux between organisms which favor higher salinity and those which favor lower salinity. If the fluctuations are extreme, appropriate salinity conditions do not last long enough for organisms to complete their life cycle, and the diversity of organisms is reduced to those few species which can tolerate the dramatic salinity fluctuations.

Even moderate releases (such as in Zone B of the regulation schedule) can transform these estuarine systems into freshwater habitats after a few weeks of sustained releases. The estuarine species are displaced or expire during extended periods of low or high salinity. In addition, continuous flow releases tend to create critically low benthic oxygen levels at the transition zone between freshwater and seawater. These ecosystem perturbations affect more than just estuarine species, since estuaries provide important nursery habitat for marine (offshore) finfish and invertebrate species. These adverse effects provided the impetus for instituting the pulse releases contained in Regulation Zone C.

In general, when regulatory releases are terminated, the salinity levels in these estuaries return to the normal range, and the ecosystems begin to recover. The estuarine species that were displaced or extirpated return or are replaced. The recovery period is commensurate with the rate and duration of the freshwater inputs to the estuaries.

Other longer-term effects of the regulatory releases from the lake on the St. Lucie and Caloosahatchee estuaries include sediment and nutrient effects. Both effects are related to the quality of the water releases from Lake Okeechobee, which contain suspended silt, clay, and organic material. Much of the suspended material settles onto the bottom of the St. Lucie Canal and the Caloosahatchee River during modest, nonregulatory releases. However, during regulatory releases – particularly the high release levels of Zone B and Zone A – this material is resuspended and carried into the estuaries during the first few days of the release period.

Suspended material increases the turbidity of the water in the estuaries and blocks sunlight to seagrass communities in these estuaries. Some seagrass communities are smothered by the suspended material as it settles in the low-energy environment of the estuaries. Other seagrass communities are affected by the reduction in sunlight that results from increased turbidity. Nutrient effects result from the nitrates and phosphorus contained in the lake water which are resuspended by the release flows and stimulate primary production in the estuaries. Releases can imbalance nutrient cycling in these ecosystems, leading to algae blooms and subsequent declines in dissolved oxygen and further increases in turbidity.

The short-term and long-term ecological problems in these estuaries are not entirely attributable to the regulatory releases from Lake Okeechobee, however. These estuaries have perturbations from other sources that contribute to the stresses on these ecosystems. For instance, other estuarine tributaries deposit freshwater, sediments, and nutrients in these ecosystems, including heavy metals that are associated with agricultural pesticide use in the contributing watersheds. These are also being addressed by the recommended plan.

E.9.3.3 Fishing and Other Economic Effects on the Estuaries

The ecological effects of the freshwater releases to the estuaries can lead to commercial and recreational fishing impacts. These potential economic effects are discussed below. There are other potential (non-fishing) economic effects from freshwater releases which are also associated with changes in estuarine water quality. These effects could include changes in (1) waterfront property values if water quality degradation is severe or sustained, (2) the quantity or quality of recreation (and tourism) if the releases discolor the water at beaches or if the releases contribute to algae blooms that limit beach access. These nonfishing effects are beyond the scope of this investigation, but they are current sources of concern to local residents and businesses who enjoy the estuaries and depend on tourists who come to use them. For example, in the spring of 1998 the City of Sanibel received complaints from residents and tourists about the water quality effects of freshwater releases down the Caloosahatchee River and into San Carlos Bay and the Gulf of Mexico.

E.9.3.4 Regulatory Release Targets for St. Lucie and Caloosahatchee Estuaries

In response to the desire to promote the health of the St. Lucie and Caloosahatchee estuaries, through the Restudy salinity distribution targets for these estuaries with associated high and low release, expressed in cubic feet per second (cfs), comprise one set of performance measures used to evaluate the alternative restoration plans (see ***Table 9.3.4-1***). The measures are the number of months that SFWMM-simulated releases exceed target release levels. The low flow targets for the two estuaries are similar. High flow targets for the St. Lucie are significantly lower than for the Caloosahatchee, since the St. Lucie estuary is a much smaller receiving water body and therefore is more effected by high freshwater releases. For both estuaries, two performance measures for large releases from the lake have also been developed, incorporating quantity thresholds and duration criteria.

TABLE 9.3.4-1
LOW FLOW & HIGH FLOW PLANNING TARGETS
ST. LUCIE AND CALOOSATCHEE ESTUARIES

ESTUARY	LOW FLOW		HIGH FLOW	
	Measure	**Target**	**Measure**	**Target**
St. Lucie	Number of Months Mean Flow < 350 cfs	50	Number of Times Mean Flow > 1600 cfs for > 14 days	13
			Number of Times Mean Monthly Flow > 1600 cfs	9
			Number of Times Mean Monthly Flow > 2500 cfs	3
Caloosahatchee	Number of Months Mean Flow < 300 cfs	60	Number of Months Mean Flow > 2800 cfs	22
			Number of Months Mean Flow > 4500 cfs	6

E.9.4 POTENTIAL EFFECTS ON FISHING IN ST. LUCIE ESTUARY

The potential economic effects of the alternative restoration plans on fishing in the St. Lucie estuary depend on how the hydrologic changes affect the ecology of the estuary and on how the ecological changes translate into changes in commercial and recreational fishing. The economic effects on commercial fishing might include changes in the size of the catch or the cost of fishing operations. For guided sportfishing, the economic effects might include changes in the income of the professional fishing guides. For recreational anglers, economic effects could result from changes in the quantity or quality of recreational fishing experiences. As evident in the discussions below, the linkages between the hydrology, ecology, and economics of fishing in the St. Lucie Estuary are highly uncertain. Nevertheless, the hydrologic information generated through the SFWMM simulations does have economic implications for fishing in the estuary.

As part of this investigation, a variety of individuals, organizations, and institutions were contacted to identify pertinent studies and individuals with expertise on the effects of Lake Okeechobee releases on the St. Lucie Estuary. Contacts included:

Florida Oceanographic Society

St. Lucie Initiative

Harbor Branch Oceanographic Institute

Marine Research Council

Indian River Lagoon National Estuary Program

Treasure Coast Regional Planning Council

St. Lucie River Coalition

Florida Marine Research Insititute

Florida Sea Grant

SFWMD

Martin County

E.9.4.1 Profile of Commercial and Recreational Fishing in the St. Lucie Estuary

A profile of commercial and recreational fishing in the St. Lucie Estuary can be constructed using field information and data from state and national fishing databases. Unfortunately, much of the available information about commercial and recreational fishing in the estuary is contained in studies and data sets for much larger geographic areas.

There is very little, if any, commercial fishing in the St. Lucie Estuary. The use of gill nets in Florida coastal waters was banned in 1994. Interviews with local fish houses (i.e., retailers) indicate that their supplies do not come from the estuary. However, there may be low levels of commercial fishing for finfish (using rod and reel or cast nets) and for crabs. In Martin County, there are 271 saltwater products licenses and 44 permits for blue crab fishing. Crabbing activity in the estuary is believed to be small.

Although there is little commercial fishing within the estuary proper, the St. Lucie Estuary has important ecological connections with offshore commercial fish stocks. As explored in Nelson et al. (1991), some commercial species of finfish and invertebrates inhabit estuaries year-round; however, a large number of species only use estuaries during portions of their life cycle. Most of these latter species fall into four general categories:

- Diadromous species, which use estuaries as migration corridors and, in some instances, nursery areas;
- Species that use estuaries for spawning, often at specific salinity levels;
- Species that spawn in marine waters near the mouths of estuaries and depend on tidal- and wind-driven currents to carry eggs, larvae, or early juveniles into estuary nursery areas; and,
- Species that enter into estuaries during certain times of the year to feed on abundant prey and/or utilize preferred habitats.

In 1990, the Indian River Lagoon, which adjoins the St. Lucie Estuary, was included in the National Estuary Program (NEP). The NEP targets nationally significant estuaries for assessment and development of management plans that will substantially enhance their ecological quality. While the NEP studies on Indian River Lagoon suggest that the freshwater flows from the St. Lucie Estuary may not significantly affect the lagoon, they do provide insight to the ecology of the St. Lucie Estuary. In particular, the Indian River Lagoon studies identified 20 species of commercial finfish and 3 species of shellfish (blue crab, hard clam, and oyster) in the lagoon that are estuarine dependent. The estuarine-dependent finfish include:

Atlantic sheephead
Bluefish
Croaker
Drum, black
Drum, red
Flounders
Jack, crevalle
King whiting
Mackerel, spanish
Menhaden
Mullet, silver
Mullet, striped
Permit
Pompano
Snapper, mangrove
Snapper, mutton
Snapper, yellowtail
Seatrout, spotted
Spot
Tripletail

Nelson et al. (1991) note that the estuaries on Florida's east coast include large numbers of tropical Caribbean fauna. In addition, they determined that the number of species – including adults, juveniles, and larvae – in southeastern estuaries varies by season and by salinity zone. Estuarine utilization for all life stages is highest in summer and lowest in winter. The number of species present as larvae reaches a peak in April in the tidal freshwater, mixing, and seawater zones. In contrast, the numbers of juveniles and adults in the three zones peak during the summer months. In any given month, more species utilize these estuaries as juveniles than at any other life stage. Some common species, such as bluefish and gray snapper, are primarily found in the estuary as juveniles and adults, with spawning, eggs, and larval development occurring offshore. Other species, such as snook and tarpon, are tolerant of a wide range of salinity levels. Seasonal variations in species composition implies that the timing – as well as the quantity – of freshwater releases to the St. Lucie Estuary are critical determinants of their potential effects on the estuarine ecology.

The Florida Department of Environmental Protection (FDEP) maintains the Florida Marine Fisheries Information System, a database of commercial fish landings. In this database, the St. Lucie Estuary is located within the Ft. Pierce fishing area, which extends approximately from Jupiter to Melbourne. Summaries of the 1993-1997 inshore commercial landings for this fishing area are presented in ***Table 9.4.1-1***. Inshore is defined as within three miles of the coast. The summaries include finfish, invertebrates, and bait shrimp. No shrimp landings were reported. The poundage, trips, and value of finfish have varied widely over the last five years, with values ranging from one-half million dollars to more than one million dollars. In contrast, the invertebrate landings showed a steady increase in all three categories.

The Ft. Pierce inshore waters landings data is complemented by ***Table 9.4.1-2***, which contains the top ten commercial landings (by weight) in Martin County during 1997. The ten listed species each account for at least two percent of the total county catch by weight (2,054,136 pounds). Together, they account for 82% of the total catch. Most of the species on this list reside in estuarine habitat for at least part of their life cycle.

TABLE 9.4.1-2
RANKED COMMERCIAL FINFISH LANDINGS BY WEIGHT
MARTIN COUNTY 1997

SPECIES	POUNDS	PERCENT OF TOTAL CATCH
Thread Herring	529,447	26%
Mackerel, Spanish	274,702	13%
Sardines	272,368	13%
Mackerel, King	134,820	7%
Shark	123,687	6%
Scad, Bigeye	88,975	4%
Mullet, Black	88,795	4%
Spot	76,135	4%
Bluefish	51,257	2%
Porgies	37,310	2%

Source: Florida DEP, Marine Fisheries Information System, 1997.

The 1997 commercial invertebrate landings for Martin County were relatively small. They included 5,245 pounds of blue crabs, 6,174 pounds of stone crabs, and 11,105 pounds of spiny lobsters. There were no shrimp landings reported in Martin County for 1997.

The St. Lucie Estuary also supports guided sportfishing and recreational fishing. According to interviews with local professional sportfishing guides, there are approximately 12 guides who operate in this estuary on a full-time basis. Charters typically fish for tarpon, spotted seatrout, snook, and red drum. Assuming that the guides charge an average of $300 per day, guided sportfishing in the estuary would have an approximate annual value in excess of $800,000. The guides indicate that while the majority of their charters consist of tourists, there are also a significant number of charters by Florida residents. Cited percentage ratios of resident/tourist charters were 40/60 for much of the year and 20/80 during the tourist season (i.e., winter and early spring).

Fishing in the St. Lucie Estuary is also popular with local anglers. Bell et al. (1982) have estimated that the overall economic value of recreational fisheries to a region can be as much as six times that from commercial fisheries. Unfortunately, no current participation rates for recreational fishing in the estuary could be identified during this investigation. However, a general impression of recreational fishing in the St. Lucie Estuary can be constructed using the following studies of recreational fishing in areas that include the estuary.

1. In a 1979 creel census of recreational anglers in the St. Lucie Estuary, Van Os et al. (1980) estimated that 338,797 fish were caught (446,820 pounds). The most abundant fish were sea catfish, but bluefish dominated the catch by weight.

2. The National Survey of Recreational Fishing conducted by the National Oceanic and Atmospheric Administration (NOAA) has collected recreational fishing data for the east and west coasts of Florida. The 1996 recreational landings for the east coast of Florida are presented in ***Table 9.4.1-3*** for those species that account for at least one percent of the total catch. Since the survey is for creeled fish, catch-and-release statistics are not available. For some gamefish, such as tarpon, catch-and-release accounts for the entire recreational fishery.

3. Bell et al. (1982) estimate 61.5% of recreational fishing trips are within brackish coastal waters or within 3 miles of shore, where fisheries stocks are largely dependent on estuaries

4. Nelson et al. (1991) describe bluefish, gray snapper, spotted seatrout, spot, black drum, red drum, and gulf flounder as among the species that are abundant in the adjacent Indian River Lagoon, and by inference, in the St. Lucie Estuary.

5. Milon and Thunberg (1993) conducted a state-wide survey of resident anglers. They estimated that, on a statewide basis, resident anglers make 8.7 fishing trips per year and that 56% of trips involved private boats. For Florida Marine Fisheries Commission Region 6, which includes the St. Lucie Estuary, Milon and Thunberg estimated over 65% of the total fishing effort was expended in near-shore waters or within the estuary or lagoon complex. Their findings suggest that over 90% of the recreational fishing by Florida residents in Region 6 is done by people who reside in the lagoon watershed. In addition, their surveys indicate that sea trout, snook, and red drum are the most popular species with anglers, pursued by 48% of the anglers who expressed species preference. The survey results suggest average statewide daily expenditures by resident anglers of $114.81, with annual expenditures of $576.49 per fisherman. This is consistent with Bell’s estimate of $508.97 spent per fisherman on recreational fishing during 1982.

6. Bell (1993) investigated fishing by tourists to Florida. He estimated that of those tourists visiting Florida, 16.5% had engaged in saltwater fishing in the last year. However, 90% of the tourist anglers do not come primarily to fish, and two-thirds of these anglers have no target species. The tourists spend approximately $110 per day while fishing.

7. Bell (1992) investigated the potential changes in tourist visitation resulting from adverse effects on recreational beaches and fisheries. He noted a statewide decline in catch per trip from 5.8 to 4.5 fish/trip from 1979-1990. However, during the same

period, he found no relationship between changes in tourism and changes in the catch rates of recreational saltwater fishing in the state.

E.9.4.2 Hydrologic Changes Associated With Alternative Restoration Plans

The SFWMM-simulated hydrologic effects of the alternative restoration plans on the St. Lucie Estuary are presented in ***Table 9.4.2-1***. The Recommended Plan is expected to produce effects equivalent to Alternative D. As indicated in this table, all of the alternative plans are expected to significantly improve upon the future without-project conditions with respect to the performance measures for low and high freshwater releases into the St. Lucie Estuary. However, none of the alternatives is expected to meet the targets for low or high water releases. In particular, the simulated high water releases of the alternative significantly exceed the performance targets for releases over 1600 cfs and over 2500 cfs.

Regarding the second performance measure in Table 9.4.2.1 (the number of times mean flow exceeds 1600 cfs for at least 14 days), the SFWMM provides insight into the source of the flows which violate the target for this measure. For each scenario, the model differentiates the inflows from the estuary's watershed from Lake Okeechobee releases. The Lake Okeechobee releases account for a relatively small percentage of the total number of times that the flow target is exceeded for each scenario: 2050 base (29 of 110: 26%); Alternatives A, C, and D (2 of 51: 4%); and Alternative B (1 of 49: 2%).

TABLE 9.4.2-1
SIMULATED HYDROLOGIC PERFORMANCE OF ALTERNATIVE PLANS
ST. LUCIE ESTUARY

PERFORMANCE MEASURE	2050 Base	ALTERNATIVE A	B	C	D & RP
Number of Months Mean Flow < 350 cfs (target: 50)	163	61	64	60	51
Number of Times Mean Flow > 1600 cfs for ≥ 14 days (target:13)	110	51	49	51	51
Number of Times Mean Monthly Flow > 1600 cfs (target: 9)	71	35	34	35	15
Number of Times Mean Monthly Flow > 2500 cfs (target: 3)	36	11	9	12	8

Note: RP = Recommended Plan (D13R + Other Project Elements)

E.9.4.3 Potential Ecological and Economic Effects of Hydrologic Changes

There has been long-standing concern about the effects of regulatory releases on the St. Lucie Estuary. More than 20 years ago, conferences were sponsored by the Florida Oceanographic Society to discuss the ecological impacts of the regulatory releases. Over the years, the level of local awareness of the issues surrounding the ecological effects of the releases has varied in accordance with the release levels.

In 1998, a number of local interests expressed concern regarding the effects of the regulatory releases. Following the extremely wet spring induced by a strong El Nino event, high lake levels required Zone A releases into the St. Lucie Estuary, reaching as high as 7,500 cfs. The brackish estuary was quickly transformed into a freshwater estuary, and the accumulated sediment on the canal bottom was quickly transported and deposited on the estuary benthos. Concern was heightened when deformed mullet and gamefish with lesions were observed in the estuary. Water samples revealed the presence of *Cryptoperidiniopsis*, a marine algae, in the estuary. *Cryptoperidiniopsis* is being investigated by FDEP as the potential cause of the lesions on fish in the estuary. However, at this time *Cryptoperidiniopsis* has not been linked to the lesions in the St. Lucie Estuary or to human health effects anywhere.

Based on available literature, some aspects of the relationship between regulatory releases and ecological effects on fishing are relatively clear. In general, the St. Lucie Estuary ecosystem is stressed by magnified oscillations in freshwater inputs to the estuary and other ecosystem perturbations. The stressors include Lake Okeechobee releases and other influences from the estuary's watershed. The variability in freshwater inputs to the estuary creates an unstable salinity environment (Chamberlain and Hayward, 1996). The turbidity and sedimentation impacts on seagrass communities may be the principal long-term concern regarding freshwater inputs to the estuary (Haunert and Startzman, 1985). However, there are also concerns about the effects of low-flow periods, particularly with regard to dissolved oxygen levels. While in some instances the effects of releases may be difficult to distinguish from watershed effects, it appears that regulatory releases do affect commercial and recreational fisheries in the estuary (Haunert and Startzman, 1980; Van Os et al., 1980).

Unfortunately, there is a great deal of uncertainty regarding the effects of the freshwater releases from Lake Okeechobee on the St. Lucie Estuary. Estuarine ecosystems are complex, and the linkages between causes (e.g., ecosystem perturbations) and effects (e.g., changes in the structure or function of the ecosystem) are often unclear. There are multiple research topics that need to be explored to fully understand these linkages. These topics include distinguishing between: (1) the impacts of regulatory releases and runoff from the watershed, (2) short-term and long-term effects of the releases, (3) the few high level releases and the more numerous smaller events, and (4) low and high flow violations of the desired salinity targets.

Ecological uncertainties compound the economic uncertainties regarding commercial and recreational fishing. An example of the relationship between uncertainties in ecological and economic response to the regulatory releases is provided by the regulatory releases which occurred during the spring of 1998. During the Spring 1998 releases, gamefish disappeared due to the salinity effects, and the commercial and recreational fishery was severely impacted. However, by June of 1998, gamefish had returned to the estuary and guided sportfishing and recreational fishing rebounded.

The economic effects would seem to be clearly bounded by the effects on fishing, since adult gamefish relocate during release periods (Van Os et al., 1980). However, the loss of juveniles and loss of habitat due to sedimentation effects on seagrass may not affect fishing and the economics of fishing for years to come. In addition, for those offshore commercial species that reside in estuarine waters during their larval or juvenile stages, the economic effects of changes in the estuarine ecology could be manifested in offshore commercial or recreational landings or in the landings of another county.

The challenge in determining the economic impacts on commercial and recreational fishing in the St. Lucie Estuary is further complicated by the need to differentiate between the with- and without-project future conditions in order to isolate the effects of the alternative restoration plans. Given these considerations, the determination of an actual dollar estimate of the effects of the alternative plans on commercial and recreational fishing is beyond the limits of this investigation. However, the hydrologic effects of the alternative plans simulated in the SFWMM can be interpreted from the perspective of the fishing industry by combining the profile of commercial and recreational fishing with the current understanding of the ecological effects of regulatory releases on the estuary.

As indicated in Table 9.4.2-1, the alternative restoration plans are all expected to result in significant improvements over the without-project future condition. However, they are not expected to meet the performance targets. The relative performances of the alternative restoration plans allow the plans to be compared, but the monetary estimation of the economic effects on the commercial and recreational fishery will require additional research into the ecology and economics of the estuary.

E.9.4.4 Further Research to Fill Data and Knowledge Gaps

The SFWMD is currently attempting to fill some of the information gaps that exist in the hydrology-ecology-economics chain of cause-and-effect as regards freshwater releases from Lake Okeechobee. In June 1998, the SFWMD sponsored a series of focus groups in Martin and St. Lucie counties that were intended to assemble local businesses affected by the large regulatory releases to the St. Lucie Estuary in the spring of 1998 and to identify the economic impacts on these businesses and the regional economy.

In general, the understanding of the hydrology/ecology/economics linkages need to be strengthened. The hydrology of regulatory and non-regulatory releases from Lake Okeechobee and the ecological effects on the estuary are an active area of research by the SFWMD, the Corps, and other agencies through the Indian River Lagoon Feasibility Study and the Lake Okeechobee Regulation Schedule Study. The focus groups will provide an effective entry point for additional studies regarding the potential economic effects of the alternative restoration plans on commercial and recreational fishing in the St. Lucie Estuary. The focus groups can help guide further economic research into the potential effects of lake releases on commercial fishing (inshore and offshore), guided sportfishing, recreational fishing, and the indirect and induced effects on the local economy. It may eventually be determined that additional research is not warranted. However, the following additional studies are identified as potential avenues to clarify the particular categories of economic effects.

Estuarine Ecology

- Continue research to differentiate effects of Lake Okeechobee freshwater releases from perturbations attributable to the watershed.

Commercial Fishing

- Inshore: Monitor the estuary for commercial fishing activities, including crab traps and cast nets.
- Offshore: analyze commercial landings of estuarine-dependent finfish and invertebrates following periods of high and low releases to determine lag effects.

Guided Sportfishing

- Survey professional guides to help determine short-term and lag effects of freshwater releases.

Recreational Fishing

- Monitor recreational catch to determine short-term and lag effects of freshwater releases.
- Survey anglers to determine willingness to pay for fishing experience.
- Conduct Boat Census: boat count, ramp count, and/or aerial surveys.

Indirect and Induced Economic Effects

- Survey local businesses to determine indirect and induced effects of changes in the number of resident and tourist fishermen.

E.9.5 POTENTIAL EFFECTS ON FISHING IN CALOOSAHATCHEE ESTUARY

While the issues regarding Lake Okeechobee releases to the Caloosahatchee Estuary are similar to the St. Lucie Estuary, there are several important differences as well. Similarities include: (1) the purposes and timing of the regulatory and non-regulatory releases from Lake Okeechobee and (2) the uncertainties in the causal relationship between hydrologic changes in the releases, the consequent ecological effects, and the economic impacts on commercial and recreational fishing. The differences include: (1) the larger size of the Caloosahatchee Estuary relative to the St. Lucie Estuary, (2) the larger releases from the lake down this waterway, and (3) the ecological distinctions between the Caloosahatchee and St. Lucie estuaries.

As part of this investigation, a variety of individuals, organizations, and institutions were contacted to identify pertinent studies and individuals with expertise regarding the impacts of the freshwater releases from Lake Okeechobee on the Caloosahatchee Estuary. Contacts included:

Harbor Branch Oceanographic Institute	Caloosahatchee River Citizens Committee
Lee County Professional Guides Association	Florida Bureau of Seafood and Aquaculture
Florida Marine Research Institute	Florida Sea Grant
City of Sanibel	Lee County
Gulf of Mexico Program	Gulf of Mexico Foundation
Charlotte Harbor National Estuary Program	Southwest Florida Regional Planning Council
Florida Center for Environmental Studies, Tarpon Bay Research Center	SFWMD

In 1995, Charlotte Harbor, which adjoins the Caloosahatchee Estuary, was included in the National Estuary Program (NEP). The Charlotte Harbor NEP effort included two studies with direct relevance for this investigation. The first is a review of the physical setting in the Caloosahatchee Estuary. The second is an estimate of the economic value of resources in the Charlotte Harbor study area, which includes the Caloosahatchee River.

Goodwin (1996) modeled the currents in the area of San Carlos Bay and concluded that much of the regulatory discharges from the Caloosahatchee River pass southward under the Sanibel Causeway and enter the Gulf of Mexico. However, under certain conditions, some of this freshwater can be transported into Pine Island Sound and Matlacha Pass. The extent of the effects of regulatory releases from the lake are variable, depending on the release rate and the wind and tidal conditions in the estuary. Based on discussions with some of the previously listed organizations, the effects of large freshwater releases, such as those experienced in the spring of 1998, extend into San Carlos Bay, Matlacha Pass, Pine Island Sound, and Estero Bay. According to local residents, the tanin-colored waters from Lake Okeechobee are quite apparent as they darken the waters of San Carlos Bay.

It appears that the sedimentation effects of the releases on the Caloosahatchee Estuary are less problematic than the nutrient effects of the releases, relative to the St. Lucie Estuary. Red tides (i.e., marine algae blooms) were consistently described during interviews as a more significant ecological and economic threat than freshwater releases from Lake Okeechobee. Red tides kill fish, ruin fishing, and close beaches with the stench of dead fish and the effects of algae on bathers' respiratory systems (e.g., throat and sinus irritation). The two issues may be interconnected, since algae blooms have been linked to nutrient inputs to coastal waters. However, there are significant sources of nutrients in these coastal waters other than water released from the lake. Phosphate mining, agriculture, and wastewater discharges contribute to the nutrient levels in the coastal waters of Lee County.

E.9.5.1 Profile of Commercial and Recreational Fisheries

As in the case of the St. Lucie Estuary, a profile of commercial and recreational fishing in the Caloosahatchee Estuary can be constructed using field information and data in national and state fishing databases. Again, much of the available information about commercial and recreational fishing in the estuary is contained in studies and data sets for larger geographic areas.

There is some commercial fishing in the Caloosahatchee Estuary. The use of cast nets in the estuary is reported to be common. In addition, there is reported to be substantial crabbing activity in the estuary. In Lee County, there are 638 saltwater products licenses and 267 permits for blue crab fishing.

The Caloosahatchee Estuary has important ecological connections with offshore commercial fish stocks. As described in Nelson (1992), many commercial finfish and invertebrate species use estuaries for critical stages of their development. Table 9.5.1-1 presents commercial landings, trips, and value data collected by the Florida DEP for the Pine Island Sound/San Carlos Bay area. As indicated in this table, in 1997 the value of the commercial landings from this area were approximately $1.7 million. The finfish and bait shrimp fisheries account for most of the landings and value. Although the shrimp landings in Table 9.5.1-1 are small, there is a significant offshore pink shrimp fishery that is based on Sanibel Island. This fishery is reflected in 1997 pink shrimp landings data for Lee County, which totaled 4,033,537 pounds. The Caloosahatchee Estuary and the area affected by freshwater releases from Lake Okeechobee comprise part of the nursery habitat for this fishery. The finfish and bait shrimp poundage, trips, and value data vary widely from year to year. This is due to changes in the fish population dynamics, fishing conditions, and fishing effort.

The data in ***Table 9.5.1-1*** are complemented by the information in ***Table 9.5.1-2*** and ***Table 9.5.1-3***. Table 9.5.1-2 contains 1997 landings data from nearby Charlotte Harbor (to the north) and Estero Bay (to the south). As indicated in Table 9.5.1-2, the finfish fishery in Charlotte Harbor is substantially larger than that of the Pine Island/San Carlos Bay area.

TABLE 9.5.1-1
COMMERCIAL LANDINGS
PINE ISLAND SOUND/SAN CARLOS BAY 1993-1997

YEAR	CATEGORY	POUNDS	TRIPS	VALUE
1993	Finfish	1,084,476	4,853	$629,297

Table 9.5.1-3 contains ranked landings of the top nine commercial species in Lee County, by weight. Each of these nine species account for at least one percent of the total county catch by weight (2,599,308 pounds). Together, they account for

95% of the total catch. Most of these species reside in estuarine habitat for at least part of their life stage. The 1997 commercial invertebrate landings for Lee County include blue crabs (1,409,015 pounds) and stone crabs (151,330 pounds). In addition, the 1997 shrimp landings for Lee County were 4,224,879 pounds.

Jack, Crevalle	33,991	1%
Ladyfish	30,758	1%
Grouper, Black	22,737	1%

Source: Florida DEP, Marine Fisheries Information System, 1997.

The Caloosahatchee Estuary also supports guided sportfishing and recreational fisheries. Nelson (1992) described the following recreational species as "highly abundant", "abundant", or "common" in the Caloosahatchee Estuary: tarpon, sea catfish, snook, crevalle jack, silver perch, pinfish, spotted seatrout, red drum, black drum, and stripped mullet.

According to interviews with the Lee County Professional Guides Association, there are approximately 60 guides who operate in Lee County, mostly on a full-time basis. Many of the guides fish in the Caloosahatchee River at least some of the time. An even larger number of guides fish in the area that is potentially subject to the effects of the lake releases. It appears that guides will frequently take charters into the Caloosahatchee River to fish for tarpon or to escape windy conditions on the coast. Guides in the area typically pursue tarpon, spotted seatrout, snook, and red drum. Assuming that the guides charge an average of $350 per day, guided sportfishing in the area would have an approximate annual revenue of $4.8 million. The guides indicate that while the majority of their charters consist of tourists, there are also significant numbers of charters by Florida residents. The ratio of resident/tourist charters of 40/60 was considered representative for much of the year, changing to 20/80 during the tourist season.

Recreational fishing in the Caloosahatchee Estuary is also popular with local anglers. Bell et al. (1982) estimated that the overall economic value of recreational fisheries to a region can be as much as six times that of commercial fisheries.

Unfortunately, no current participation rates for recreational fishing in the estuary were identified as part of this investigation. However, a representative picture of recreational fishing in the Caloosahatchee Estuary can be constructed using studies of recreational fishing that include the estuary.

1. The 1996 National Survey of Recreational Fishing conducted by the NOAA for the west coast of Florida is presented in ***Table 9.5.1-4*** for those species which account for at least one percent of the catch. Many of those species spend much of their lives in estuarine waters.

TABLE 9.5.1-4

Source: NOAA. National Survey of Recreational Marine Fishing. 1996.

2. Bell et al. (1982) estimated that 61.5% of recreational fishing trips are within brackish coastal waters or within 3 miles of shore, where fish stocks are largely dependent on estuaries

3. The state-wide survey of resident anglers by Milon and Thunberg (1993) estimated that for the Florida Marine Fisheries Commission Region 3, which includes the Caloosahatchee Estuary, over 65% of the total fishing effort was expended in near-shore waters or within the estuary or lagoon complex. Their findings suggest that 88% of the recreational fishing by Florida residents in the lagoon is done by people who reside in the region. In addition, their surveys indicate that sea trout, snook, and red drum are the most popular species with anglers, pursued by 48% of the anglers who expressed species preference.

4. Bell's (1993) study of fishing by Florida tourists estimated that 16.5% of tourists visiting Florida engaged in saltwater fishing in the last year. However, 90% of

the tourist anglers do not come primarily to fish, and two-thirds of these anglers have no target species.

Lee County is also home to an emerging aquaculture industry. Since the State of Florida instituted the gill net ban in 1994, it has encouraged aquaculture to mitigate the economic effects on watermen and coastal communities and to meet the growing demand for seafood. In Lee County, there are over 10 aquaculture farms, which primarily raise hard clams. The Harbor Branch Oceanographic Institute has received a state grant to provide technical support for clam aquaculture. Some of these operations raise seed clams for sale to other aquaculture farmers; others raise mature clams for commercial sale. The seed clam operations typically use a closed (recycling) water system. The clam farms which are raising mature clams in Lee County are located in Pine Island Sound near the midpoint of Pine Island. It is anticipated that the releases from Lake Okeechobee will not have a significant effect on aquaculture operations in Lee County for two reasons: (1) the seed clams, which are potentially vulnerable to sudden and drastic salinity changes, are not exposed to the freshwater releases from the Caloosahatchee River and (2) the clam farms that raise clams to maturity are sufficiently removed from the more extreme effects of the freshwater releases.

E.9.5.2 Hydrologic Changes Associated With Alternative Restoration Plans

The SFWMM-simulated hydrologic effects of the alternative restoration plans on the Caloosahatchee Estuary are presented in ***Table 9.5.2-1***. The Recommended Plan is expected to produce effects equivalent to Alternative D. As indicated in this table, all of the alternative plans are expected to significantly exceed (improve upon) the future without-project conditions with respect to the performance measures for low and high freshwater releases into the Caloosahatchee Estuary. Each of the alternative plans also meets the performance targets, and even improves on them. The extreme high and low flow rates are exceeded fewer times than the targets allow in all cases.

Regarding the second performance measure in Table 9.5.2-1 (the number of months when the mean flow exceeds 2800 cfs), the SFWMM provides insight into the source of the flows which exceed the maximum flow rate for this measure. For each scenario, the model differentiates the inflows from the estuary's watershed from Lake Okeechobee releases. The Lake Okeechobee releases account for a relatively small percentage of the total number of times that the flow target is exceeded in the SFWMM scenarios: 2050 base (17 of 61: 28%) and Alternatives A, B, C, and D (1 of 11: 9%).

TABLE 9.5.2-1
SIMULATED HYDROLOGIC PERFORMANCE OF ALTERNATIVE PLANS
CALOOSAHATCHEE ESTUARY

PERFORMANCE MEASURE	2050 Base	ALTERNATIVE			
		A	B	C	D & RP
Number of Months Mean Flow < 300 cfs (target: 60)	111	36	36	36	36
Number of Months Mean Flow > 2800 cfs (target: 22)	61	11	11	11	11
Number of Months Mean Flow > 4500 cfs (target: 6)	26	4	2	3	3

Note: RP = Recommended Plan (D13R + Other Project Elements)

E.9.5.3 Potential Ecological and Economic Effects On Fishing In Caloosahatchee Estuary

Based on available literature, some aspects of the relationship between the regulatory releases and effects on fishing are relatively clear. In general, the Caloosahatchee Estuary ecosystem is stressed by the magnified oscillations in freshwater inputs to the estuary and other ecosystem perturbations. The stressors include the Lake Okeechobee releases and other influences from the estuary's contributing watershed. As in the St. Lucie Estuary, the variability in freshwater inputs to the Caloosahatchee Estuary creates an unstable salinity environment. The work of Doering and Chamberlain (1997) suggests that turbidity and dissolved oxygen levels are comparable to other Florida estuaries, but nitrogen concentrations are relatively high. They also note that, in general, water quality deteriorates with distance upstream from the mouth of the estuary. While in some instances the effects of the releases may be difficult to distinguish from effects of the Caloosahatchee River's relatively large watershed, it appears that the regulatory releases affect the commercial and recreational fisheries in the estuary.

Unfortunately, as in the case of the St. Lucie Estuary, there is a great deal of uncertainty regarding the effects of the freshwater releases from Lake Okeechobee on the Caloosahatchee Estuary. Estuarine ecosystems are complex, and the linkages between causes (e.g., ecosystem perturbations) and effects (e.g., changes in the structure or function of the ecosystem) are often unclear. There are multiple research topics that need to be explored to fully understand these linkages. These topics include distinguishing between the effects of: (1) the impacts of lake releases and freshwater inflow from the watershed, (2) short-term and long-term effects of the releases, (3) the few high level releases and the more numerous smaller events, and (4) low and high flow violations of the desired salinity envelope.

The ecological uncertainties compound the economic uncertainties regarding commercial and recreational fishing. As in the St. Lucie Estuary, the return of gamefish following a period of large releases to the estuary may not fully reflect the impacts on the fisheries. The economic effects would seem to be clearly bounded by the effects on fishing, since adult gamefish relocate during release periods (Van Os et al., 1980). However, the loss of juveniles and loss of habitat due to impacts on seagrass communities may not affect fishing and the economics of fishing for years to come.

The challenge in estimating the economic effects on commercial and recreational fishing in the Caloosahatchee Estuary is further complicated by the need to differentiate between the with- and without-project future conditions in order to isolate the effects of the alternative restoration plans. Given these considerations, the determination of a dollar value of the effects of the alternative plans is beyond the scope of this investigation. However, the simulated hydrologic effects of the alternative plans can be interpreted from the perspective of the economics of commercial fishing by combining the profile of commercial and recreational fishing with current understanding of the ecological effects of regulatory releases on the estuary.

As indicated in Table 9.5.2-1, the alternative restoration plans are expected to result in significant improvements over the without-project future condition with respect to low and high water inputs to the Caloosahatchee Estuary. They are also expected to meet, and even improve upon, the performance targets. The relative performances of the alternative restoration plans allow the plans to be ranked, but the monetary estimation of the economic effects on the commercial and recreational fishery will require additional research into the ecology and economics of the estuary.

E.9.5.4 Further Research to Fill Data and Knowledge Gaps

As in the case of economic effects in the St. Lucie Estuary, understanding of the causal linkages between hydrology/ecology/economics needs to be strengthened for the Caloosahatchee Estuary. The SFWMD is currently attempting to fill some of the information gaps that exist in describing the sequence of hydrology-ecology-economics effects of freshwater releases from Lake Okeechobee. In particular, the SFWMD is conducting research on the ecological effects of the freshwater releases on the Caloosahatchee estuary. It appears that the economic effects need to be further explored. One avenue would be to hold a similar series of focus groups in Lee County as are being conducted for the St. Lucie Estuary. The regulatory releases in the spring of 1998 provide timely opportunity to explore the economic impacts of these releases.

The following recommendations are offered to further understanding of the economic impacts of the freshwater releases from Lake Okeechobee into the

Caloosahatchee Estuary. Many of these recommendations coincide with suggestions for the St. Lucie Estuary. All of this research must consider the area potentially impacted by the releases, not just the physical limits of the estuary.

Estuarine Ecology

- Continue research to differentiate effects of Lake Okeechobee freshwater releases from perturbations attributable to the watershed.

Commercial Fishing

- Inshore: Monitor the estuary for commercial fishing activities, including crab traps and cast nets.

- Offshore: analyze commercial landings of estuarine-dependent finfish and invertebrates following periods of high and low releases to determine lag effects.

Guided Sportfishing

- Survey professional guides to determine short-term and lag effects of freshwater releases.

Recreational Fishing

- Monitor recreational catch to determine short-term and lag effects of freshwater releases.

- Survey anglers to determine willingness to pay for fishing experience.

- Conduct Boat Census: boat count, ramp count, and/or aerial surveys.

Indirect and Induced Economic Effects

- Survey local businesses to help determine indirect and induced effects of changes in the number of resident and tourist fishermen.

E.9.6 FRESHWATER FLOWS TO BISCAYNE AND FLORIDA BAYS

For commercial and recreational fishing in Biscayne Bay and Florida Bay, the sequence of effects of the alternative restoration plans also depends on how the hydrologic changes affect the ecology of the bays and how the ecological changes translate into changes in commercial and recreational fishing. However, the bays have several important differences relative to the St. Lucie and Caloosahatchee estuaries. First, the bays lie at the downstream terminuses of the C&SF system where water flowing through the Everglades enters the sea. Second, the bays, which primarily lie within the Biscayne National Park and Everglades National Park, are recognized as estuaries of national and international significance. Third, the bays are much larger than the St. Lucie and Caloosahatchee estuaries. As a result, they play a much more significant role in south Florida's commercial and recreational fishing.

The bays support a variety of recreation activities, including fishing, spearfishing, boating, diving, and snorkeling. In addition to their ecological roles in supporting in-shore and off-shore commercial and recreational fishing, the bays provide non-fishing recreation activities, such as boating, snorkeling, and diving. The economic values of these activities are potentially significant. These recreation activities could be affected by short-term and long-term ecological changes associated with modifying freshwater releases to the bays. However, estimating the economic effects of restoration-related impacts on the quantity and quality of these non-fishing activities in the bays is problematic. For this reason the discussions of recreation in the bays focuses on sportfishing. Nevertheless, it is assumed that ecological impacts of restoration on the bay fisheries will have associated effects on snorkeling and diving activities.

As in the cases of the St. Lucie and Caloosahatchee estuaries, the quantity and timing of freshwater flows into Biscayne and Florida bays are critical determinants of the structure and function of the bay ecosystems. The bays differ from the two smaller estuaries, since they do not experience the magnified fluctuations of high and low freshwater inputs and resultant salinity levels. Instead, the bays in general receive less water throughout the year than they would under natural conditions. Another distinction of the bays is the greater significance of groundwater flows as freshwater inputs to these estuaries.

The sizes, locations, and protected status of Biscayne Bay and Florida Bay make them critical components of the marine ecosystem in the Florida Keys and south Florida. The waters surrounding the Florida Keys are recognized as one of the nation's most significant and most stressed marine resources (Ault et al., forthcoming). Many ecologically and economically important tropical marine fish and invertebrates recruit over protracted periods of the year to avoid predation or take advantage of prey (Ault et al, forthcoming). However, many economically important south Florida fishes (including groupers, snappers, grunts) and invertebrates (lobsters and shrimp) spawn offshore at the shelf edge and their larvae are then advected inshore into nearshore and coastal bay nursery areas (Lee et al., 1992). As described by Ault et al. (1997), the potential effects of the alternative restoration plans encompass the entire Keys ecosystem:

> *Hydrologic (Everglades Restoration) projects of historic proportions are expected to make a substantial change in the timing, volume, and location of freshwater outflows into the coastal marine environment. These changes could affect the survivorship of juvenile reef fishes in important shallow nursery areas of Florida Bay and Biscayne Bay and ultimately affect the productivity of the entire coral reef ecosystem.*

E.9.7 POTENTIAL EFFECTS ON FISHING IN BISCAYNE BAY

Biscayne Bay is a shallow subtropical estuary that is approximately 38 miles long and 11 miles wide at its broadest. The northern part of the bay is a state-designated aquatic preserve. The southern part of the bay includes Biscayne National Park. The extreme southern portion of the bay, which includes Card Sound and Barnes Sound, lies outside of the park. Less than five miles east of the park lies the northern boundary of the Florida Keys coral reef tract. The park consists of 180,000 acres of which 95% is water. While there is a visitor center, visitors must use a boat to access most of the park.

As in the case of the two preceding estuaries, the quantity and timing of freshwater inputs to Biscayne Bay are critical determinants of the ecosystem structure and function. In its natural condition, Biscayne Bay was fed by overland sheetflow and groundwater discharges through permeable rock formations. The urbanization of Miami-Dade County and the modification of the hydrology of south Florida have significantly impacted the ecology of Biscayne Bay by focusing surface water inputs to canal outlets and reducing groundwater discharges to the bay. The current surface discharges are greater than under natural conditions, and the canal discharges are irregular pulses that quickly and drastically change salinity levels inconfined portions of the bay (Serafy et al, 1997). Rapid salinity fluctuations can represent significant – even lethal – stress for marine organisms, reducing available energy for growth, development, and resistance to other stressors, such as high temperature. Serafy et al. (1997) found that areas of the bay that are subject to the low salinity pulses from the canals have significantly less ecological diversity and productivity, since species that are intolerant to rapid salinity fluctuations must expend energy to respond to the stress or relocate to areas with more stable salinity.

E.9.7.1 Profile of Commercial and Recreational Fishing in Biscayne Bay

A profile of commercial and recreational fishing in Biscayne Bay can be constructed using a variety of information from Biscayne National Park, FDEP, and estuarine ecologists at the Rosenstiel School of Marine and Atmospheric Sciences at the University of Miami, such as Dr. Jerald Ault. As in the cases of the previous two estuaries, Biscayne Bay supports commercial and recreational fisheries on-site and serves as important nursery habitat for offshore fisheries as well. The bay includes a variety of habitats that support extensive fisheries, including bay, seagrass flats, reef, and pelagic.

In their survey of estuaries on the southeastern coast of the U.S., Nelson et al. (1991) describe the following species as among those that are “highly abundant”, “abundant”, or “common” in Biscayne Bay.

Snapper, gray	Seatrout, spotted
Flounder, gulf	Mullet, striped
Ladyfish	Crab, blue
Pinfish	Shrimp, pink
Mackerel, spanish	Shrimp, grass
Spot	

In contrast to the St. Lucie and Caloosahatchee estuaries, there is commercial landings information that specifically apply to Biscayne Bay. Table 9.7.1-1 presents commercial landings data for Biscayne Bay, Card Sound, and Barnes Sound, including annual poundage, trips, and value for the 1993-1997 period. The 1997 value of the commercial fishery was in excess of $1.5 million. The bait shrimp fishery accounted for the dominant share of this value with 73%, as compared to invertebrates (21%), finfish (4%), and shrimp (2%). The value of the bait shrimp fishery has been growing in value during the 1993-1997 period. In contrast, the value of the pink shrimp fishery has been declining steadily during the same period.

The 1997 commercial landings data for Miami-Dade County provide additional insight into commercial fishing in Biscayne Bay. ***Table 9.7.1-2*** contains 1997 commercial landings for the twelve species in Miami-Dade County each of which accounts for at least two percent of the total catch by weight. The percentages of total county catch by weight (696,882 pounds) are also included in this table. Together, these twelve species account for 83% of the total catch. As indicated in ***Table 9.7.1-2***, king mackerel is the dominant commercial species by weight, followed by ballyhoo, yellowtail snapper, shark, and amberjacks. Most of the species in Table 9.7.1-2 spend part of their life in coastal estuaries such as Biscayne Bay or depend on the shrimp stocks that thrive in the seagrass beds of these estuaries and support the coastal and offshore food chains.

In addition to the commercial finfish landings, Miami-Dade County had invertebrate landings that included: blue crabs (104,248 pounds), stone crabs (85,050 pounds), and spiny lobsters (399,598 pounds). The 1997 commercial shrimp landings for the county were 349,271 pounds.

Mullet, silver	17,887	3%
Snapper, gray	15,371	2%

Biscayne Bay supports an extensive guided sportfishery. Inshore species that are pursued by guided anglers include: bonefish, red drum, snook, black drum, tarpon. Bonefish are a particularly large and valuable fishery for professional fishing guides. No permits from Biscayne National Park are required for a guide to operate in Biscayne Bay. Therefore, the exact number of guides is not known, but discussions with guides who regularly operate in Biscayne Bay suggest that there are approximately 20 guides who operate in Biscayne Bay on a full time basis. At approximately $300 per day, the guided sportfishery would have an approximate annual value of $1.4 million.

In the annual fisheries report for Biscayne National Park, Lockwood and Perry (1997) describe the size and diversity of the park's recreational fishery. In 1996, over 55,000 boats used park waters. Of these boats, 59% (32,875) were engaged in recreational fishing. Most of the fishermen were residents of Homestead (44%) or Miami (39%). Less than 0.5% were from north Florida or from out of state. Surveys with bay fishermen suggest that 45% have no species preference, while others target specific species: dolphin (18.4%), bonefish (5.8%), lobster (5.5%), and snapper (4.1%).

Table 9.7.1-3 presents the annual number of boats, total catch, and total harvest for groupers, snapper, grunts, and other species during the 1996-1997 period. Grunts dominated the catch and harvest in terms of number of fish. Lockwood and Perry (1997) report no change in abundance of recreational catch from 1992-1996. The top three species by catch in the "other" species category are blue runner (36.4%), barracuda (16.4%), and pinfish (4.7%). Based on their recreational creel survey, Lockwood and Perry (1997) estimate the following species composition for inshore waters in the park: grunt (41.2%), snapper (28.6%), lobster (7.2%), jacks (7.1%), grouper (6.0%), barracuda (2.8%), hogfish (1.6%), and others (5.5%).

TABLE 9.7.1-3
ANNUAL RECREATIONAL CATCH AND HARVEST
BISCAYNE NATIONAL PARK
1996-1997

SPECIES	FISHING BOATS (% of total)	TOTAL CATCH (fish)	TOTAL HARVEST (fish)
Groupers	17,470 (53%)	37,327	4,320
Snappers	20,057 (61%)	145,005	34,455
Grunts	19,307 (59%)	220,960	108,665
Other	24,817 (75%)	145,005	34,455

Source: Lockwood and Perry (1997)

If each of the 32,875 boats which visited Biscayne Bay in 1996 had an average of 2.3 fishermen per boat (consistent with the Everglades National Park recreational fishery), there were approximately 74,087 fishermen involved in the bay's recreational fishery. If the estimated daily expenditures per fishing trip by Florida resident ($114.81) from Milon and Thunberg (1993) is applied to these fishermen, the recreational fishery in 1996 had an approximate value of $8,505,928.

Biscayne National Park is a sanctuary for lobster from commercial trapping. However, recreational lobster catch is permitted. For the 1996-1997 period, Lockwood and Perry (1997) present an annual estimate of 11,455 man-hours for sport lobstering in the park involving 4,552 boats. The estimated harvest was 44,710 lobsters.

Spearfishing is also permitted in Biscayne National Park. For the 1996-1997 period, Lockwood and Perry (1997) present an annual estimate of 8,316 man-hours for spearfishing involving 5,398 boats. The estimated catch was 16,729 fish, and the estimated harvest was 15,370 fish.

E.9.7.2 Hydrologic Changes Associated With Alternative Plans

The SFWMM simulates freshwater inputs to Biscayne Bay using flows at five different discharge points: Snake Creek, North Bay, Miami River, Central Bay, and South Bay. For four of these discharges, the Restudy team has established targets for wet and dry season releases into the bay. These targets and the results of the simulations for the with- and without-project future conditions are contained in ***Table 9.7.2-1***. The Recommended Plan is expected to produce effects equivalent to

Alternative D. In general, the 2050 base conditions and the alternative restoration plans fall short for the target discharges (wet and dry seasons). In addition, three of the alternative restoration plans are expected to have less desirable performance than the without-project conditions. The exception is Alternative D.

TABLE 9.7.2-1
SIMULATED HYDROLOGIC PERFORMANCE OF ALTERNATIVE PLANS
SURFACE WATER FLOWS TO BISCAYNE BAY
(1000 acre-feet)

SURFACE DISCHARGES	SEASON	TARGETS	2050 BASE	ALTERNATIVES			
				A	B	C	D & RP
Snake Creek	Dry	93	43	14	29	31	28
	Wet	67	114	57	83	87	83

	Wet	158	152	122	125	175	208

Note: RP = Recommended Plan (D13R + Other Project Elements)

E.9.7.3 Potential Ecological and Economic Effects On Fishing In Biscayne Bay

The potential shortfall of the with- and without-project conditions relative to the targets for freshwater inputs to Biscayne Bay suggest a continued salinity stress on the bay ecosystem. This stress may have ecological effects that infer economic consequences for commercial and recreational fishing in the bay. From an ecological point of view, the response of seagrass communities to continued salinity stress will be critical, since these communities support juvenile pink shrimp which are critical to the health of the inshore and offshore fisheries.

The relatively stable abundance of economically valuable species suggests that the ecosystem has some resilience to the continued salinity stress from low freshwater inputs. However, the sustainability of this abundance under continued stress is not known.

Alternative D is clearly the most preferable of the alternative restoration plans. It is the only alternative plan that provides more freshwater inputs to Biscayne Bay than the without-project conditions.

E.9.7.4 Further Research to Fill Data and Knowledge Gaps

Biscayne Bay is the subject of ongoing research regarding the structure and function of this ecosystem. This research will help link the changes in hydrology associated with the alternative restoration plans with the potential economic effects on commercial and recreational fishing. The economics of recreational fishing and guided sportfishing appear to be the least understood links in the sequence of effects from hydrologic to ecological to economic. Surveys of professional guides, their charters, and recreational anglers could be directed toward determining the value and satisfaction of their fishing experience.

E.9.8 POTENTIAL EFFECTS ON FISHING IN FLORIDA BAY

Florida Bay is a triangularly-shaped subtropical lagoonal estuary that is approximately 700 square miles in area. To the north is the Florida mainland; to the southeast is the Florida Keys. Over 80% of the bay lies within the Everglades National Park. The bay is shallow with an average depth of less than one meter. There are over 200 small islands in the bay which are rimmed with mangroves and have interior, irregularly flooded flats.

As in the cases of the preceding estuaries, the quantity and timing of freshwater inputs to Florida Bay are critical determinants of the ecosystem structure and function. At the northern edge of the bay lies the interface of the bay with the Everglades. Freshwater inputs to the bay occur via: (1) sheetflow across the marl prairies of the southern Everglades, (2) creeks fed by Shark River Slough and Taylor Slough, and (3) groundwater flow through porous rock formations (McIvor et al., 1997). Some areas within the bay become hypersaline when evaporation exceeds freshwater inputs to the bay (via rainwater and surface and groundwater flow from the Everglades). The hypersalinity is reinforced by circulation patterns within the bay that limit flushing of hypersaline water.

Based on Restudy model results, freshwater flow to Florida Bay has been decreasing in recent years. For instance, it is estimated that flows of Shark River Slough into Florida Bay have decreased 59% relative to natural conditions (McIvor et al., 1997). Banding of bay coral formations is one example of available biological evidence. The reduced freshwater inputs to the bay diminish the diversity and productivity of this estuary, since many species found in Florida Bay are not well adapted to hypersaline conditions.

The reduction in freshwater flows into the bay may be related to the widespread dieoff of seagrass in the bay which began in 1987 and continues today. Prior to that time, seagrass covered more than 80% of the bay, supporting shrimp populations that comprise critical elements of the inshore and offshore food chains. In some areas, vegetative cover has been re-established by the original species or by other species. However, in other areas, re-colonization has been slow, and large areas of the bottom are devoid of vegetation. The seagrass dieoff may be attributable to causes other than changes in the quantity or timing of freshwater inputs to the bay, but the long-term salinity stress may have exacerbated their vulnerability to other perturbations (e.g., high water temperature, reduced frequency of hurricanes, pathogens). In addition to the seagrass dieoff, increases in sponge mortality and algae blooms also indicate that the ecology of this estuary is under stress.

E.9.8.1 Profile of Commercial and Recreational Fishing in Florida Bay

Florida Bay supports large commercial and recreational fisheries inshore and offshore. Commercial fishing in the Everglades National Park portion of the bay was banned in 1985. In the 10 years prior to the ban (1976-1985), the commercial harvest in the bay had averaged over two million pounds per year (Centaur Associates, 1986). Currently, the bay is heavily used as a recreational fishery for Florida residents and tourists, many of whom hire professional sportfishing guides. In their survey of estuaries on the southeastern coast of the U.S., Nelson et al. (1992) describe the following species as among those that are “highly abundant”, “abundant”, or “common” in Florida Bay. McIvor et al. (1997) add grunts, lobster, and barracuda to this list of species that are common in Florida Bay, either as juveniles or adults.

Pink shrimp
Grass shrimp
Blue crab
Stone crab
Bull shark
Tarpon
Hardhead Catfish
Silversides
Snook
Bluefish
Jack, crevalle
Gulf flounder
Pompano
Snapper, gray
Sheepshead
Pinfish
Silver perch
Spotted seatrout
Spot
Drum, black
Drum, red
Mullet, striped
Mackerel, spanish

Florida Bay provides important habitat for many offshore commercial species, especially pink shrimp and stone crabs. Table 9.8.1-1 presents commercial landings information for Florida Bay and oceanside waters of the Keys, including annual poundage, trips, and value for 1993-1997. Since commercial fishing is not permitted in Everglades National Park, the commercial landings data in this table apply to those areas of the bay which lie outside of the park. In 1997, the value of commercial fishing in Florida Bay was approximately $10.8 million. As indicated in ***Table 9.8.1-1***, the value of the invertebrate fishery, which is dominated by lobsters and stone crabs, far exceeds the value of the commercial finfishery. In 1997, the finfish landings dropped well below 1993-1996 levels.

Table 9.8.1-2 presents 1997 commercial finfish landings data for the 13 species in Monroe County that account for at least two percent of the county landings by weight. Together, these 13 species account for 87% of the total catch. As indicated in this table, yellowtail snapper is the dominant commercial species by weight in Monroe County, followed by king mackerel, ballyhoo, and dolphin. Most of the species in Table 9.8.1-2 spend part of their life in coastal estuaries such as Florida Bay or depend on the shrimp stocks that thrive in the seagrass beds of the bay and support the coastal and offshore food chains.

The 1997 commercial invertebrate landings for Monroe County include: stone crabs (2,410,204 pounds) and spiny lobster (64,441,159 pounds). Total 1997 shrimp landings for Monroe County were 3,693,854 pounds.

Grunts	122,466	2%

Guided sportfishing is extremely popular in Florida Bay. The guides are required to have a permit from Everglades National Park to operate within the park's bay jurisdiction. In 1996, the park issued 202 guide permits. Discussions with representatives of the Florida Keys Fishing Guides Association suggest that there are approximately 170 guides operating in the Florida Keys, most of which fish in Florida Bay at least some of the time. Most of the Keys guides operate from Islamorada. Most of the non-Keys guides that operate in Florida Bay are based in Everglades City. The guide anglers typically pursue bonefish, tarpon, snook, and snapper. Bonefish and tarpon are particularly large and valuable fisheries for professional fishing guides. These species are of little food value and are generally not highly sought by non-guide anglers.

In the 1996 annual fisheries report for Everglades National Park, Schmidt et al. (1997) estimated that there were 26,279 fishing boats with an average of 2.3 fishermen per boat for a total of 61,354 anglers. There were an estimated 351,163 hours of fishing in the Florida Bay portion of the park in 1996. The average trip lasted a total of 7.2 hours (with 5.8 hours of fishing) and caught 20 fish. In the park, Flamingo is the most popular access point to Florida Bay used by 50 to 60 percent of park anglers. Most of the anglers fishing in the park are from south Florida. The Flamingo survey suggests that 84% of fishermen are from south Florida with only 1% from out of state. Many of the Florida Bay anglers (45%) do not have any target species when they go fishing. In general, recreational anglers pursue the "Big Four" species: sea trout, red drum, snook, and gray snapper.

As in the case of Biscayne Bay, the estimated daily expenditures of a Florida resident per fishing trip ($114.81) from Milon and Thunberg (1993) can be used to estimate the value of the recreational fishery in the Everglades National Park portion of Florida Bay. Based on the park's estimate of 61,354 fishermen, the recreational fishery in the park portion of the bay in 1996 had an approximate value of over $7 million.

The 1996 recreational catch and harvest for the most popular gamefish species are presented in ***Table 9.8.1-3***. This table includes guide and non-guide anglers. Spotted seatrout led the 1996 catch and harvest. Schmidt et al. (1997) indicate that catch rates for seatrout, red drum, snook, and snapper were nearly as high or higher than during the 1986-1990 period (1991-1994 estimates were not available). The catch rates for bonefish and tarpon are also relatively stable.

In 1996, the professional guides conducted 3,378 fishing trips with an average of 2.1 persons fishing. As a result, the guide anglers catch and harvest estimates in Table 9.8.1-3 represent the effort of approximately 13,965 fisherman. At approximately $300 per day, the guided sportfishery in 1996 had an approximate value of $1.0 million.

TABLE 9.8.1-3
ESTIMATED FLORIDA BAY RECREATIONAL CATCH AND HARVEST
EVERGLADES NATIONAL PARK 1996

E.9.8.2 Hydrologic Changes Associated With The Alternative Plans

The SFWMM simulates freshwater inputs to Florida Bay using wet season (June – October) and dry season (November - May) flows at four different discharge transects: Shark River Slough into Whitewater Bay and Craighead Basin, Taylor Slough, and Eastern Panhandle into Florida Bay. The SFWMM simulates overland and groundwater flows for the three discharge points into Florida Bay. The benchmarks for these discharges are the flows that were simulated in the Natural System Model (NSM). For some measures in ***Table 9.8.2-1***, such as overland flow through Shark River Slough, the alternative restoration plans are expected to provide more freshwater inputs to Florida Bay than the 2050 without-project (base) conditions, but less than the amount estimated in the NSM. In other cases, such as southward flows via Craighead Basin, the with- and without-project conditions are expected to provide greater freshwater inputs to the bay than under natural conditions. While the hydrologic performance of the individual restoration plans are mixed, it appears that for most of the hydrologic measures, Alternative A is superior to the other restoration plans and to the future without-project conditions. The Recommended Plan is expected to produce effects equivalent to Alternative D.

TABLE 9.8.2-1
SIMULATED HYDROLOGIC PERFORMANCE OF ALTERNATIVE PLANS
FLORIDA BAY AVERAGE ANNUAL FLOWS
(1000 acre-feet)

AVERAGE ANNUAL FLOWS	FLOW TYPE	SEASON	NSM	2050 BASE	ALTERNATIVES A	B	C	D & RP

E.9.8.3 Potential Ecological and Economic Effects On Fishing In Florida Bay

The importance of commercial and recreational fishing in Florida Bay to the economies of the Florida Keys and south Florida have been previously documented by Leeworthy and Wiley (1996 a, b; 1997 a, b) and Gorte (1994). The complex hydrologic effects of the alternative restoration plans challenge estimation of (1) the potential ecological effects on Florida Bay and (2) the potential economic impacts on commercial and recreational fishing.

For commercial fishing, the nursery function of Florida Bay for the offshore fisheries would be enhanced if freshwater inputs to the bay resembled those under the natural system. From an ecological perspective, the quantity of water is not the only important aspect of the freshwater inputs. The timing and routes of the freshwater inflows are also critical determinants of the diversity and productivity of the bay ecosystem.

The best available economic linkages between Florida Bay and the offshore commercial fisheries is provided by the pink shrimp fishery on the Tortugas grounds. Based on the work of Browder (1985) and others, pink shrimp catch rates and landings on the Tortugas grounds are influenced by freshwater inflows to Florida Bay, which provideS nursery habitat for juvenile pink shrimp. Browder's efforts to directly link the freshwater inflows and pink shrimp catch rates on the Tortugas grounds implicitly includes the intermediate salinity effects of the inflows and the consequent ecological impacts. Pink shrimp catch rates (in pounds per vessel per day) were adopted as a performance measure by the Restudy team to evaluate the economic effects of the alternative restoration plans. The team used a historic catch of 134 pounds per vessel per day. In recent years, this fishery has experienced a significant decline in landings from 17.6 million pounds from 1971-1985 to 12.2 million pounds (1986-1990), a decline of more than 30% (Gorte, 1994). For additional treatment of the pink shrimp fishery, see Sheridan, P., 1996. For the 2050 future conditions, the SFWMM simulations generate the following results for average daily pink shrimp catch rates per vessel per year: 2050 Base conditions (88 pounds), Alternative A (128 pounds), Alternative B (122 pounds), Alternative C (137 pounds), and Alternative D (137 pounds). The Recommended Plan is expected to produce effects equivalent to Alternative D. All of the alternative restoration plans are expected to result in improvements in pink shrimp catch rates compared to the without-project future condition.

Although Alternative A appears to have a strong hydrologic performance in terms of freshwater inputs to Florida Bay (see Table 9.8.2-1), Alternatives C and D are expected to produce the highest pink shrimp catch rates of the alternative restoration plans. The reason is that the statistical relationship used by the SFWMM to predict pink shrimp catch rates and freshwater inputs includes Key West air temperature as well as freshwater flows into the bay. Key West air temperature serves as a proxy for water temperature in the bay. The simulated superiority of Alternatives C and D provide a cautionary illustration regarding ecological and economic interpretation of hydrologic information.

Regarding the recreational fishery, the increases in freshwater inputs to Florida Bay that could accompany the alternative restoration plans would be expected to improve the ecology of the bay and the abundance of gamefish. Rutherford et al. (1989) found a positive correlation between catch rates of spotted seatrout in Florida Bay and rainfall in prior years (2 and 3 years). Tilmant et al. (1989) found that recreational fishermen caught significantly more red drum in Florida Bay when the preceding year had experienced high rainfall. As with the bay ecology, the degree of improvement in gamefish abundance would depend on the quantity, timing, and routes of the freshwater inputs, as well as other environmental factors. It must be recognized that cause and effect relationships in estuarine ecology are complex. The freshwater inputs are one factor in the complex interaction of environmental influences on the ecology of Florida Bay.

E.9.8.4 Further Research To Fill Data and Knowledge Gaps

Florida Bay is the subject of wide-ranging ecological and economic research. The ecological research is coordinated by the Florida Bay Program Management Committee, an interagency committee of federal and state agencies with jurisdictional or scientific interest in Florida Bay. In its annual Strategic Science Plan, the committee prioritizes Florida Bay research needs and identifies information gaps. In addition, the committee draws upon the experience of a national scientific oversight panel and sponsors an annual Florida Bay Science Conference. In cooperation with the Program Management Committee, the Everglades National Park is developing a marine monitoring network for temperature and salinity, dividing the bay into zones where recorders can correlate catch with conditions in the bay.

The economic significance of Florida Bay has also been the subject of several investigations in recent years (Gorte, 1994; Leeworthy and Wiley, 1996 a, b and 1997 a, b). As a result of these studies and ongoing efforts by the Everglades National Park to monitor recreational fishing in the bay, the economics of fishing in Florida Bay are relatively well defined. The most important knowledge gap regarding the potential economic effects of the Everglades restoration plans seems to be the variation of fish abundance with freshwater inputs to the bay. This is the subject of ongoing research, and additional data collection and analysis is required to strengthen understanding of the hydrologic/ecological/economic sequence of effects.

E.9.9 SUMMARY OF POTENTIAL ECONOMIC EFFECTS ON FISHING

The potential effects of the Restudy's alternative restoration plans are summarized in ***Table 9.9-1***. This table presents estimates of current annual revenues for each of the fisheries under consideration. As described in the above discussions, these estimates were generated using a variety of approaches and data sources. Consequently, the estimates should be considered approximate, and comparisons of the revenues of one fishery with another should be made with caution. Table 9.9-1 also contains information on the anticipated hydrologic performance of the alternative restoration plans. In general, the alternative plans are expected to comprise improvements over the without-project (base) future conditions. As indicated in the table, Alternative D is expected to have the most desirable hydrologic performance among the alternative plans. The Recommended Plan is expected to produce effects equivalent to Alternative D. However, the plans are not expected to provide inputs to the St. Lucie Estuary that meet the Restudy planning targets or NSM flows. The economic interpretation of this hydrologic information suggests that the alternative plans could result in significant improvements in the economics of commercial and recreational fishing relative to the existing and without-project future conditions. The quantification of the expected economic impacts is not possible at this time given knowledge and data gaps in the sequence of hydrologic, ecological, and economic effects that determine economic impacts of the alternative restoration plans.

TABLE 9.9-1
SUMMARY OF ECONOMIC EFFECTS OF ALTERNATIVE PLANS ON COMMERCIAL AND RECREATIONAL FISHING

Area	Approximate Annual Revenues of Fishery ($ million)			Hydrologic Performance Of Alternative Plans			Economic Interpretation of Hydrologic Performance
	Commercial	Guided	Recreational	Performance Relative to 2050 Base	Ranking	Performance Relative to Targets/NSM	
Lake Okeechobee	$2.3	n.a.	$671	A,B,C, & D exceed 2050 Base conditions	A – 2 B – 3 C – 2 D – 1	n.a.	Minor positive economic impacts expected with alternative plans.
St. Lucie Estuary	$1.7	$0.8	n.a.	A,B,C, & D exceed 2050 Base conditions	A – 4 B – 2 C – 3 D – 1	A,B,C, & D do not meet flow targets	Significant positive economic impacts expected with alternative plans.
Caloosahatchee Estuary	$1.7	$4.8	n.a.	A,B,C, & D exceed 2050 Base conditions	A – 3 B – 1 C – 2 D – 2	A,B,C, & D meet flow targets	Significant positive economic impacts expected with alternative plans.
Biscayne Bay	$1.5	$1.4	$8.5	Only D exceeds 2050 Base conditions	A – 4 B – 3 C – 2 D – 1	A,B,C, & D do not meet flow targets	With the exception of Alternative D[1/] significant negative economic impacts expected with alternative plans
Florida Bay	$10.8	$1.0	$7.0	A,B,C, & D exceed 2050 Base conditions	A – 1 B – 2 C – 4 D – 3	A,B,C, & D do not meet NSM flows	Significant positive economic impacts expected with alternative plans.

Note: Recommended Plan effects expected to be equivalent to D.

[1/] Biscayne Bay is expected to have positive impacts with Alternative D and the Recommended Plan (the only alternatives to do so), although there are multiple performance measures, and the results are mixed.

E.10 COSTS

Data for initial construction/implementation, land acquisition, monitoring, and periodically recurring costs for OMRR&R (operation, maintenance, repair, replacement, and rehabilitation), have been developed through engineering design and cost estimation, and real estate appraisal efforts. Details of that data development are explained and discussed elsewhere in this report. The main issues requiring economic evaluation attention include present worth calculations, price levels, and timing of project spending.

Costs represent the difference between conditions without any plan (the "base condition", or "without-project condition") and with a plan or alternative. For purposes of this report and analysis, NED costs (National Economic Development Costs, as defined by Federal and Corps of Engineers policy), are expressed in 1999 price levels, and are based generally on costs estimated to be incurred over a 50 year period of analysis. Costs of a plan represent the value of goods and services required to implement and operate/maintain the plan.

The timing of a plan's costs is important. Construction and other initial implementation costs cannot simply be added to periodically recurring costs for project operation, maintenance, and monitoring. Also, construction costs incurred in a given year of the project can't simply be added to construction costs incurred in other years if meaningful and direct comparisons of the costs of the different alternatives are to be made. A common practice of equating sums of money across time with their equivalent at an earlier single point in time is the process known as discounting. Through this mathematical process, which involves the use of an interest rate (or discount rate) officially prescribed by Federal policy for use in water resource planning analysis (currently set at 6.875% per year), the cost time streams of each alternative are mathematically translated into a present worth value. This present worth value, calculated for this study as of the beginning of the period of analysis, can then be directly and meaningfully compared between the plans being considered in this study. An annual value, equivalent to the present worth, can also be computed for the 50 year period of analysis. This average annual value represents an equivalent way of expressing the costs of a plan. The various costs estimated to be incurred over time to put each plan into place and keep it going will be computed and expressed as both a present worth value and an average annual equivalent value.

There is some admitted uncertainty as to how any of the plans, if approved and adopted, would be implemented. It is recognized that any of the plans would likely be implemented over a considerable period of time, little by little. For purposes of this evaluation, construction and land costs are assumed to be incurred on an equal annual basis during the first 20 years of the 50 year period of analysis (i.e., for each of the first 20 years of the period of analysis, 1/20th of the construction and land totals is the estimated amount to be spent).

OMRR&R costs, which have been estimated as an annual amount for a fully implemented, fully functioning plan, would begin only after implementation of project features have reached completion. For purposes of this analysis, these costs are assumed to begin to be incurred after the initial two years of construction activity have passed. Calculation of the present worth and average annual equivalent values of the OMRR&R costs are based on the assumption that the annual costs would grow by an equal amount each year (i.e., linear growth through time), reaching 100% of the full OMRR&R estimated amount 19 years later, in the 2nd year following completion of project implementation.

An important feature of all alternatives is that of monitoring programs, needed to acquire knowledge of project effectiveness. Such information can then be used to make needed changes and adjustments in the future. The costs of such programs must be accounted for and are part of the costs of alternatives. For purposes of this analysis, the annual estimated monitoring cost for each alternative is estimated to be incurred at 100% of the same estimated level starting with the first year of the period of analysis, and continuing at that level throughout the 50-year period of analysis.

Present worth calculations assume that costs are incurred at mid-year. The calculations convert all costs from the middle of the year in which they are spent to an equivalent amount at a common time reference point. For purposes of this study, this common time reference point is the beginning of project construction.

A summary of NED project implementation, OMRR&R, and monitoring costs for Plans A, B, C, and D, and their derived present worth and average annual equivalent values, is outlined in ***Tables10-1*** and ***10-2***.

Table 10-1
Summary of Costs of Plans A-D

Plan	**Cost (millions)**			
	Initial		**Periodically Recurring**	
	Land	**Construction**	**OMRR&R**	**Monitoring**
A	$1,444	$3,785	$70	$10
B	$1,645	$4,378	$72	$10
C	$1,673	$5,052	$126	$10
D	$1,709	$5,626	$162	$10

Note: Initial cost represents total cost of project; periodically recurring cost represents 100% of full annual amount. Costs reflect estimated 1999 prices.

Table 10-2
Present Worth and
Average Annual Equivalent Costs of Plans A-D

Plan	Costs (Millions)	
	Present Worth	**Average Annual Equivalent**
A	$3,524	$251
B	$3,979	$284
C	$4,746	$338
D	$5,333	$380

Note: 1999 prices, annual discount rate = 6.875%, 50 year period of analysis; all plans have 20 year construction period, with all implementation costs spread uniformly over the 20 year period; OMRR&R starts following the 2nd year of implementation (which is also the 2nd year of the period of analysis), initially = 1/20th of the full OMRR&R estimate, growing by 1/20th of the full OMRR&R each year until the full level of OMRR&R is reached, after which OMRR&R remains at that level for the remainder of the period of analysis; monitoring costs are constant each year throughout the period of analysis; all costs assumed to be incurred at mid-year. E.g., present worth = [$(1.06875)^{-.5}$ + $(1.06875)^{-1.5}$ + $(1.06875)^{-2.5}$ + … + $(1.06875)^{-19.5}$] x (land + construction costs)/20 + [$(1.06875)^{-2.5}$ x (1/20) + $(1.06875)^{-3.5}$ x (2/20) + $(1.06875)^{-4.5}$ x (3/20) + … + $(1.06875)^{-21.5}$ x (20/20)] x (full annual OMRR&R estimate) + [$(1.06875)^{-22.5}$ + $(1.06875)^{-23.5}$ + $(1.06875)^{-24.5}$ + … + $(1.06875)^{-49.5}$] x (full annual OMRR&R estimate) + [$(1.06875)^{-.5}$ + $(1.06875)^{-15}$ + $(1.06875)^{-2.5}$ + … + $(1.06875)^{-49.5}$] x (annual monitoring cost estimate). Average annual equivalent = (present worth) x [.06875 x $(1.06875^{50})/(1.06875^{50} - 1)$].

A summary of NED project implementation, OMRR&R, and monitoring costs for the Recommended Plan and their derived present worth and average annual equivalent values, is outlined in the ***Table 10-3***. The Recommended Plan is a modification of Plan D above. It has been "fine-tuned" to improve its overall performance and acceptability, and contains a number of "other project elements" ("OPE's"), most of which are separable, stand-alone projects which could be undertaken with or without any of the basic plans, and which would contribute to environmental improvements in the overall study area. The summary cost data for the Recommended Plan is presented separately because its costs are not comparable with the costs of Plans A through D, mainly because of the inclusion of the OPE costs.

Table 10-3
Present Worth and
Average Annual Equivalent Costs of Recommended Plan

Category	Costs (Millions)		
	Amount	**Present Worth**	**Average Annual Equivalent**
Land	$2,221	$1,292	$92
Construction	$5,598	$3,031	$216
Total Initial	**$7,820**	**$4,323**	**$308**
OMRR&R	$173	$1,209	$86
Monitoring	$10	$145	$10
Total Recurring	**$183**	**$1,354**	**$96**
TOTAL		**$5, 677**	**$404**

Note: Recommended Plan = D13R + Other Project Elements

As mentioned previously, there is uncertainty as to how long it would take to complete project implementation, and the 20 year construction period assumption used in the above calculations has been used as a potential most likely scenario. It is important to recognize the sensitivity of present worth and average annual equivalent values of the costs of alternatives to variations in this assumption. To this end, a second set of calculations was performed based on the general assumption of a 50 year, instead of a 20 year implementation period. The relative differences between the present worth values of the alternatives is almost exactly the same for the 50 year implementation period assumption, as for the 20 year assumption. The same holds true for the average annual equivalent costs of the alternatives. Using the 50 year assumption, the present worth values are about half of what they are using the 20 year assumption. The same holds true for the average annual equivalent costs.

E.11 REGIONAL ECONOMIC IMPACTS

E.11.1 INTRODUCTION

The purpose of this section is to evaluate and quantify the economic consequences of the restoration plans on the economy of South Florida. Primary and secondary consequences of the proposed structural and operational modifications of the C&SF system will be considered. Primary consequences include the economic activities stimulated by the purchases of materials and services required in the construction of the project, the purchases of real estate, operation and maintenance of the system and monitoring costs. Secondary consequences are the changes outlined in Section E.1.5.4 and in Figure 1.5.4-1 above, such as the effects on agricultural and urban areas, commercial navigation, fishing, recreation, and flooding. Of these, only the consequences of changing agricultural land use and of altered water deliveries to agriculture will be estimated at this time.

The study region of the impact analysis is defined in Section E.11.2. Five types of economic impacts are defined and quantified in Section E.11.3. The general methodology used in the evaluation of regional impacts with simple numerical examples drawn from South Florida is explained in Section E.11.4. The results of the computations are presented in Section E.11.5.

E.11.2 DEFINING THE STUDY AREA

The study area for the restoration plan coincides with boundaries of the South Florida Water Management District (SFWMD), which is composed of ten full counties and parts of six other counties. However, the national and state statistical systems that provide the data for the regional economic analysis make it impractical to isolate the economic activities of *parts* of counties. Therefore, if a significant share of a "partial" county's economic activity falls within the SFWMD, the entire county is included in the study area, while those counties with only a small share of economic activity falling within the SFWMD will be excluded. Using these criteria, two of the "partial" counties –Okeechobee and Osceola-- are included in the study area along with the ten "full" counties of Broward, Collier, Dade, Glades, Hendry, Lee, Martin, Monroe, Palm Beach, and St. Lucie. The four partial counties that are excluded are Charlotte, Highlands, Orange, and Polk.

The twelve counties that fall within the study region account for 87.9% of the area, 97% of the population, and 96% of the water demand of the total SFWMD. (See Table 11.2-1, lines 1b,2b, & 3b.) The counties in the study area account for 26.2% of the state's total area, 39.2% of the state's

TABLE 11.2-1
ECONOMIC CHARACTERISTICS OF THE STUDY AREA

	1995		2010	
	Estimate	Region as % of Total	Estimate	Region as % of Total
	[1]	[2]	[3]	[4]
1. Area (square miles)				
a. Study Area (12 full counties)	14,164	100.0		
b. SFWMD (10 full & 6 partial counties)	16,114	87.9		
c. Total Florida	53,997	26.2		
2. Population (million)				
a. Study Area (12 full counties)	5.556	100.0	6.880	100.0
b. SFWMD (10 full & 6 partial counties)	5.729	97.0	7.110	97.8
c. Total Florida	14.184	39.2	17.836	38.6
3. Total Water Demands (billion gals/year)*				
a. Study Area (12 full counties)	1,236	100.0	1,657.00	100.0
b. SFWMD (10 full & 6 partial counties)	1,285	96.1	1,725.00	96.1
c. Total Florida	2,768	44.6	n.a.	n.a.
4. Regional Economic Characteristics	% of State			
a. Employment (millions)	2.935	38.7		
b. Numer of Housholds (millions)	2.346	39.3		
c. Total Personal Income (billion $)	$142.53	43.6		
d. Income per household ($)	$60,750	111.1		

12 Counties included in the Impact Study Area: Broward, Collier, Dade, Glades, Hendry, Lee, Martin, Monroe, Okeechobee, Osceola, Palm Beach, and St. Lucie.
4 Counties excluded from Study Area but partially within SFWMD: Charlotte, Highlands, Orange, Polk.
*Note: Lines 3a-c refer to 1990.
Sources:
Data for the partial counties in col.1of lines 1b & 2b were computed by multiplying the shares of the area and population that fall within the SFWMD by their respective total county population & area.
Shares for the partial counties are from SFWMD, Water Supply Needs and Sources 1990-2010, (July 1992). County totals are IMPLAN data.
Line 2 for 2010 are medium projections from Florida Bureauof Economic and Business Research (BEBR), 1997 Florida Statistical Abstract, Table 1.84.
Line 3 from SFWMD, Water Supply, Table A.1. All Florida totals from BEBR, 1997 Fl.Stat.Abst., Table 8.40.

population, and 44.6% of the state's total demand for water. (See lines 1c, 2c, & 3c of Table 11.2-1.)

Over 5.6 million people with a total personal income of $142.5 billion live in the study area. This corresponds to 2.3 million households with an average income of $60,750 per family, which is 11.1% higher than the state-wide average.[3] (See Table 11.2-1, lines 4a & b, cols. 1 & 2.)

No attempt has been made to identify economic impacts of the restoration plan on subregions or on groups of counties within the study area for two reasons. First, the present plan is unable to pinpoint the exact location of construction and the annual maintenance expenditures. Second, the actual locations of direct effects of changes in the agricultural and urban water supplies are based on the 4-square mile grid cells defined in the SFWMM model and their effects on households or industries cannot be separated. Therefore, only the impacts on the entire region will be evaluated.

While the location of the various impacts will eventually depend on the exact placement of the components, the magnitude of the economic impacts on the total region may be evaluated in relation to their causes. These cover a range of anticipated effects, each of which will be investigated in some depth. First are the impacts due to the actual construction costs of all the components of each alternative. Second are the impacts due to the costs of the land purchases required by the components for each alternative. Next are two categories of impacts associated with the changes in use of the acquired lands. In the case of agricultural land, there will be a reduction in agricultural produce as the land is put into the alternative use of water storage. There will also be improvements in productivity on other agricultural lands due to more regular water deliveries. Two additional categories of costs will occur on an annual basis once the project begins: the cost of monitoring the project and the cost associated with operating and maintaining the components of each alternative. Each of these categories is discussed in the next section.

E.11.3 THE IMPACT CATEGORIES

The five categories of impacts that will be considered are: (a) impacts due to construction activities; (b) impacts due to real estate purchases; (c) impacts due to

---

[3] See Bureau of Economic and Business Research, 1996 and 1997 Florida Statistical Abstract, Table 24.74, in each annual volume for price levels for only two areas within Florida. The Consumer Price Index (CPI) of the Miami-Ft. Lauderdale area rose by 4% from an initial level of 148.9 in 1995 to 153.7 in 1996. This is compared to the CPI of the Tampa-St. Peterburg-Clearwater area, which rose by only 1.5% from an initial level of 129.7 in 1995 to 131.6 in 1996. Thus, the cost of living in the Tampa area in 1995 was 12.9% lower than the Miami area. By 1996, the gap in the cost of living between the two areas had risen to 14.4%. The appearance of higher household income in the study area may be due to higher prices in South Florida. Once these differences in prices are considered, the average household income in South Florida, which is 11.1% *higher* than the state average, might actually mean a *lower* standard of living.

changing land use; (d) impacts due to altered water deliveries; and (e) impacts due to monitoring costs.

E.11.3.1 Construction

Construction costs, the most significant of the five impact categories, were derived by summing up the costs of all the plan features for each alternative. These were estimated by summing the detailed line items of each feature.[4] Each line item was also allocated to one of 528 sectors of the IMPLAN[5] regional economic model, and these were aggregated to give total construction costs for all the features in each alternative in terms of economic sectors. Cost characteristics of six prototypical structures are given in Table 11.3.1-1.

Total costs for each of these structures are summarized in Table 11.3.1-2. Panel I of that table indicates the capacity, number, or volume of each design feature, for example, 61,152 to 92,538 cfs (cubic feet per second) of new pump capacity, 282,000 to 513,000 feet (that is, 53-97 miles) of new channels, and a total of 104,500 to 250,500 feet (that is, 20 to 47.5 miles) of seepage barriers and curtain walls.

The total costs of the first five types of structures account for about a third of the total cost of each alternative. The remaining costs are incurred by the Aquifer Storage and Recovery (ASR) facilities, seepage barriers, and, in Alternative D-13R, "other project elements."

---

[4] To facilitate these computations, a profile of costs for each prototypical structure was made which classified all the items of that structure according to their economic sector. The total number of structures of each type was then calculated for each alternative. Total construction costs were thus recomputed in terms of the 528 economic sectors.

[5] Impact Analysis for Planning (IMPLAN), a static input-output regional economic model originally developed by the U.S. Forest Service. Current software and data is maintained by the Minnesota IMPLAN Group (MIG) in Stillwater, MN. See [www.IMPLAN.com].

Table 11.3.1-1
Cost Characteristics of Six Prototypical Structures

STRUCTURE	CHARACTERISTIC	ESTIMATED COST
A. Pumping Plant	74 different pumping stations designed, ranging from 50 to 4800 cubic feet per second (cfs). Costs assigned to 17 IMPLAN sectors & labor.	$12,102 per 1,000 cfs
B. Spillways	50 different spillways designed, varying by cfs and by number and size of gates. Costs assigned to 18 IMPLAN sectors & labor.	$3,303 per 2 gated spillway
C. Culverts	59 different projects, involving culverts ranging from 2-7 barrels, 70' to 300' long, & 48"-96" in diameter. Costs assigned to 9 IMPLAN sectors and labor Road costs assigned to 4 IMPLAN sectors & labor.	$149.90 per 70 ft. culvert
D. Channels and Canals	59 new canal structures, plus fills & enlargements, varying by length, width at top & bottom, and by depth. Costs assigned to 6 IMPLAN sectors & labor.	$174,000 per 500 ft.
E. Levees	45 projects plus rerouting, removing, and degrading of existing levees. Cost varies by length, height, surface area, and footprint area (acres). Costs assigned to 8 IMPLAN sectors & labor.	$30.0 million per 125,000 ft.
F. Aquifer Storage & Recovery (ASR)	11 projects, ranging from 315-355 wells per alternative. Costs assigned to 3 IMPLAN sectors.	$173 million per 5 MGD well

*Columns may not sum due to rounding.

E.11.3.2 Real Estate & Effects Of Other Land Acquisitions

The impacts of the sale of large tracts of real estate on the economy may be several types. The sale of land may be regarded as a simple change in which the owner held the value in real estate and now holds an equal value in cash. If the cash is spent locally or reinvested in regional enterprise, then new economic activity might be stimulated in the region and even more funds might be leveraged by the enterprise. For example, the sale of the Talisman sugar lands in the EAA by its owner, the St. Joe Corporation, is augmenting the company's investments in housing and other new developments throughout Florida.[6]

[6] See, for example, "A Land Giant is Stirring. Will Florida Ever Be the Same?" New York Times, Sunday, April 12, 1998, Business Section, p. 1.

When land sales also result in the transfer of fresh money into regional banks a general economic expansion in the region is supported through the banking multiplier if the local banks invest these new funds locally. If, however, landowners reside elsewhere or hold their funds in other regions, then the expansionary effects of large transfers of funds will not occur in the study area.

Due to the ambiguity of the ultimate use of real estate funds, the expenditures on land were treated as purchases in the real estate sector of the IMPLAN regional economic model and thus generates employment and income similar to other "productive" sectors. The effects of monetary expansion through the local banking system are not captured in the IMPLAN model.

Real estate purchases do, however, affect the use of land, for example, by changing agricultural land into water storage areas. Therefore, the impacts of the alternatives involve a reduction in agricultural production on the converted lands and an increase in agricultural production in other lands due to the additional supply of water and the improved regularity of water deliveries there.

The effects of converting 15,040 acres of pasture, 30,000 acres of citrus groves, 80,000-82,000 acres of sugarcane, and 1,660 acres of row corps into water storage areas may have yet other effects. If none of the converted land is replaced, the total agricultural output would decline in the future due to the land's withdrawal from cultivation. If, however, agricultural production shifts from the acquired lands to other lands within the study area that are not presently cultivated, then the purchase price of the land has served as a one-time payment for the relocation of agriculture, and there is no net decline in regional agricultural output.

The above alternative may be realistic for all the lands needed by the restoration project with the exception of the proposed purchase of 60,000 acres of prime sugar lands in the EAA. Here, the production of sugarcane is in close proximity to the processing mills, and the migration of sugar cultivation west of the EAA into Hendry County could result in serious loss of efficiency to existing mill capacity.

The region's six mills (excluding Talisman, which is concluding its operations in the coming few years) draw their cane from a total of 438,000 acres of planted sugarcane.[7] This means that, on the average, each mill draws on 73,000 acres of cane fields for its operation. In reality, the capacities of the existing mills range by a factor of almost three, the smallest being the Atlantic's mill in Belle Glade, which ground 1.2 million tons in the 1995/96 season, to U.S. Sugar's Clewiston's mill which ground 3.4 million tons.[8]

[7] Florida Sugar Cane League, "Forida Sugar Industry Production, 1976-1996."
[8] "Florida Factory Index," Gilmore Sugar Manual 1996/97, Fargo, ND: Sugar Publications, 1997, pp. 71-96.

The withdrawal of 60,000 acres from sugar production could imply a decline of 2.02 million tons of sugar for grinding or about 14% of the total sugar crop.[9] However, improvements in water deliveries to the remaining sugar lands, increased acreage and the expansion of mill capacity near the newly opened land, and the conversion to more productive strains of sugarcane could all offset the reduction of output due to land purchases.

The regional economic model will be used to compute the impacts due to agricultural land purchases according to two alternative assumptions. The first is to reduce the annual sales of the region by the total value of all the affected crops in each of the plans. The second alternative assumption and more likely scenario assumes that the sale of only the 60,000 acres of sugarcane will not be replaced by production elsewhere, and that the impact of this reduction does not extend forward into processing or milling. For all the alternative plans, the remainder of agriculture will enjoy higher yields due to improved deliveries of water as computed in the SWFFM model, and this is computed separately.

Total real estate purchases are estimated to range from $1.4 to $2.3 billion, which, spread over 20 years, would amount to $72.2 - $116.0 million per year. If production on the EAA sugarlands is not replaced elsewhere, then the reduction in agricultural output is estimated to be $84.7 million per year. The gains to the remaining agricultural lands from improved water deliveries are estimated to be around $2 million per year, for all the alternatives.

E.11.3.3 Operation And Maintenance (O & M)

O & M costs were estimated for each component of each alternative. These were aggregated into 6 IMPLAN sectors for all the components plus labor. These totals and their distribution are given in Table 11.3.3. The largest single item in the O & M budget will be the maintenance and operation of the Aquifer Storage and Recovery (ASR) facilities. This will range from 48% to 72 % of the total annual O & M budget across the alternatives.

E.11.3.4 Total Project Costs and Annual Project Costs

Total construction and real estate costs for the alternatives are summarized in Table 11.3.4, lines 1.A and B. These are annualized over 20 years in lines 2.A and B. The other categories of annual costs include the costs due to possible agricultural reductions (line C), costs (or benefits) due to improved water deliveries (line D), monitoring costs (line E), and O & M costs (line F).

[9] Calculated at 33.7 tons of cane per acre, the average of the past five harvests, 1992/93 to 1996/97.

(2) all agric. land losses	481,781	533,079	624,291	690,746	743,319

E.11.4 THE METHOD OF REGIONAL IMPACT ANALYSIS

E.11.4.1 The Chain Of Inputs

The types of economic impacts that a new project can have on output, earnings, and jobs in a region are known as “direct,” “indirect,” and “induced.” “Direct” impacts are caused by first round of expenditure of the project. The “indirect” impacts count only the inputs which are purchased as a result of the first round expenditures. The importance of these “indirect” effects will vary with the complexity of production in the study area and the degree to which required materials are supplied by local producers.

The direct and indirect impacts are concerned primarily with the chains of production. For example, expenditure of $100 million for the construction of a new utility will require purchases of concrete, one of its key inputs. The production of concrete, in turn, requires inputs of sand and gravel, the mining of which requires purchases of petroleum fuel, and so on through many stages. A simple direct chain for six such stages is pictured in Figure 11.4.1-1, in which the percentage given below the label in each box represents the share of gross inputs accounted for by that sector. For example, in the case of stage 2.0, “concrete products” accounts for only 2.0% of all inputs that go into the making of “new utility structures.” In the preceding stage 3.0, “sand and gravel” accounts for only 3.1% of all inputs that are required by “concrete products.”

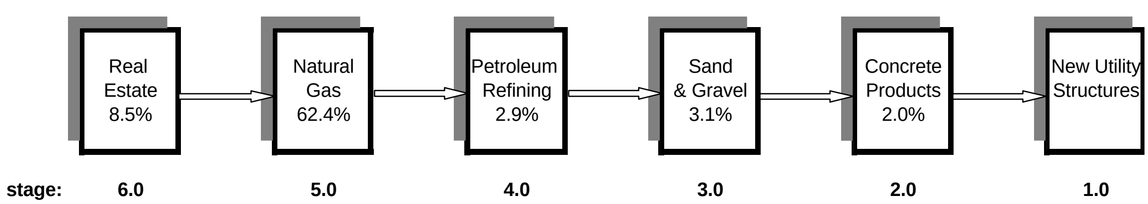

FIGURE 11.4.1-1
THE PRIMARY CHAIN OF INPUTS: SIX STAGES
SOUTH FLORIDA CONSTRUCTION

Clearly, many other inputs besides those pictured in Figure 11.4.1-1 are needed for each stage. In stage 2.0, for example, in addition to concrete products, other significant intermediate inputs include communication services, fabricated structures, non-ferrous wire drawing, architectural services, management consulting, and wholesale trade, and these are shown in stage 2.0 of Figure 11.4.1-2. Each of these seven stage 2.0 inputs in turn requires inputs. Some of the detailed "links behind the primary chain" are pictured as stages 3.0 and 4.0 in Figure 11.4.1-2. As in the previous figure, the percentage given below the label in each box represents the share of gross inputs accounted for by that particular sector.

Only a fraction of the indirect effects are shown in Figure 11.4.1-2, and these may be very complicated, depending on the technological needs of each sector and their location within the region. If intermediate suppliers have settled in the region, then the chain of production may be richly developed and intricate. If the suppliers are outside the region, the resulting chain could be very truncated and the indirect impacts sparse. Figure 11.4.1-2 depicts seven of the stage 2.0 intermediate suppliers for "new utility structures" but only two of the stage 3.0 and stage 4.0 suppliers for each of the stage 2.0 sectors. In reality, each stage consists of hundreds of different inputs, depending on the level of detail of the model and the "chains" that are located within the region.

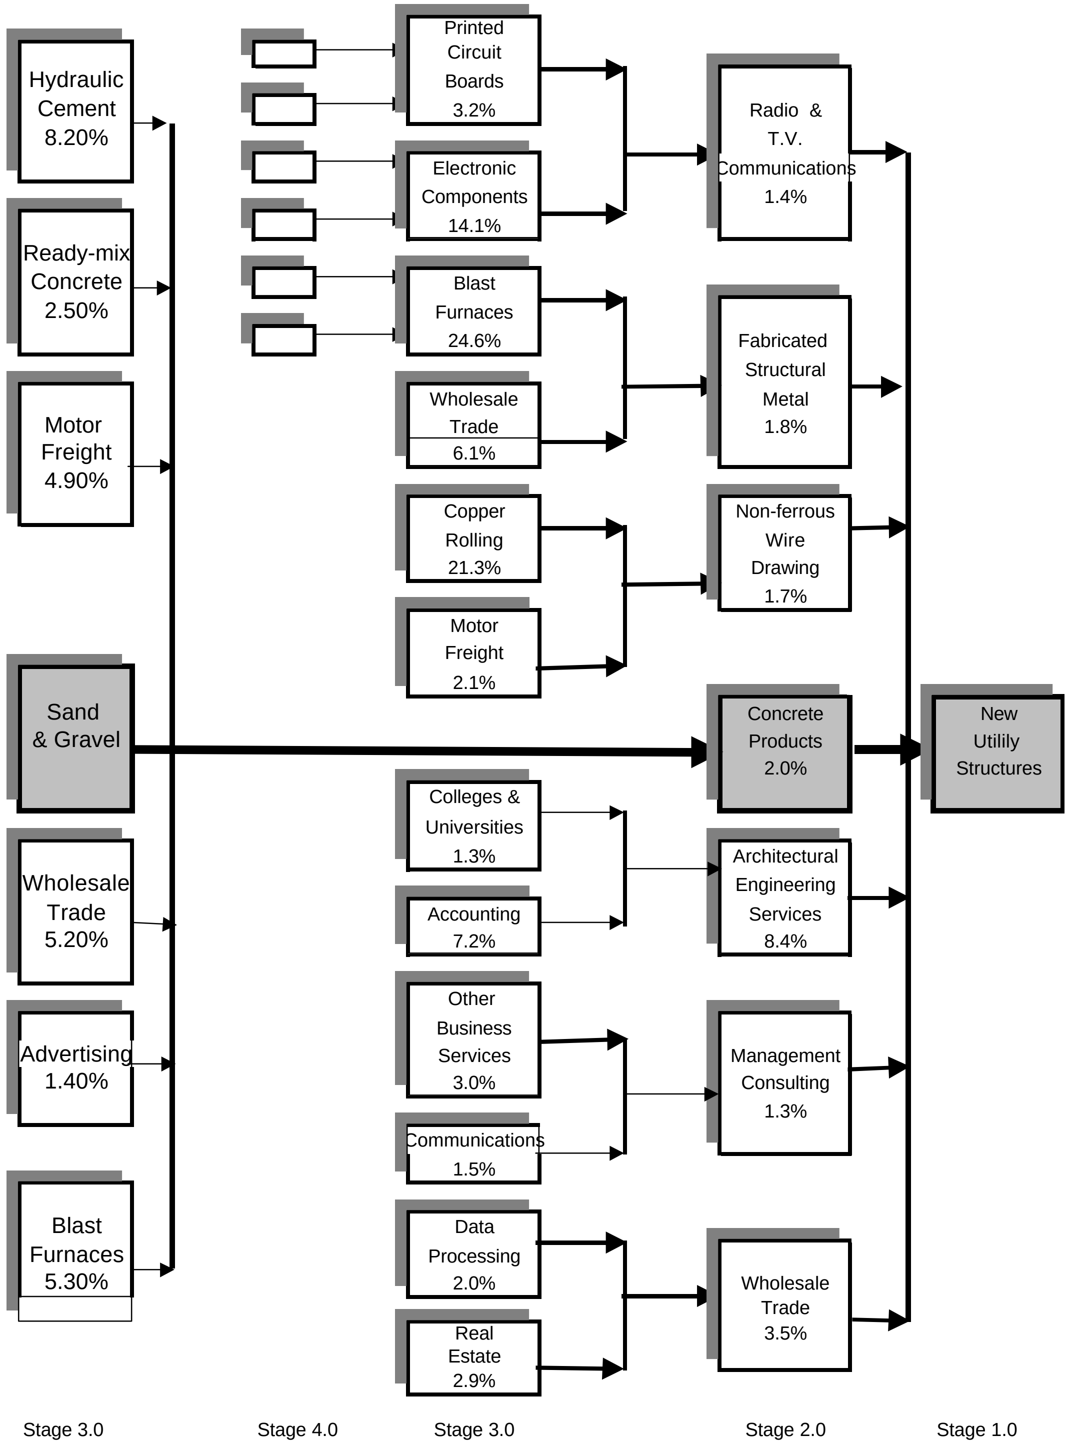

FIGURE 11.4.1-2
LINKS BEHIND THE PRIMARY CHAIN

Thus far, the analysis has dealt only with purchases that enterprises make of other enterprises. In addition to these "intermediate" inputs, each sector also employs workers directly, pays rent and taxes, and earns profits on the invested capital. These are the categories of "value added" (as opposed to "intermediate" or already-fabricated) inputs. Each of the rectangular-shaped sectors depicted in Figures 11.4.1-1 and 11.4.1-2, therefore, also requires these "value added" or primary inputs which are represented in Figure 11.4.1-3 as the parallelograms beneath the rectangles of the chain of direct or indirect inputs.

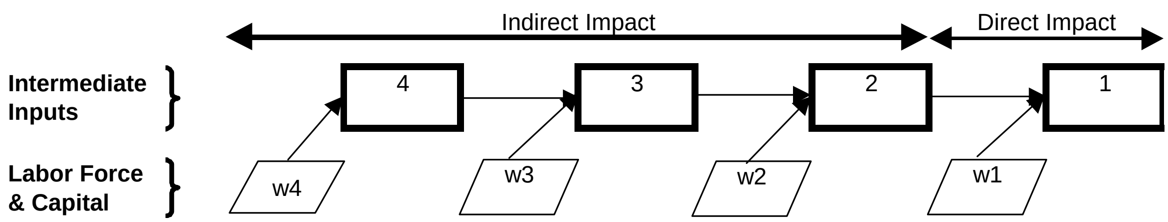

FIGURE 11.4.1-3
THE CHAIN WITH PRIMARY INPUTS INCLUDED

"Induced" impacts are the cumulative economic effects that result from the spending of the workers' earnings. This is illustrated in Figure 11.4.1-4 by the sales of bread from sector 5 to all the workers, W1 – W4, who are employed in sectors 1-4, plus the sale of flour, sector 6 together with its millers, W6, and the sale of grain, sector 7 with its farmers, W7. Bread may be sold to workers W5, W6, and W7, and this would also be counted in the induced impact. The regional model does not trace the feedbacks of the other categories of value-added, such as rent, taxes, and profits.

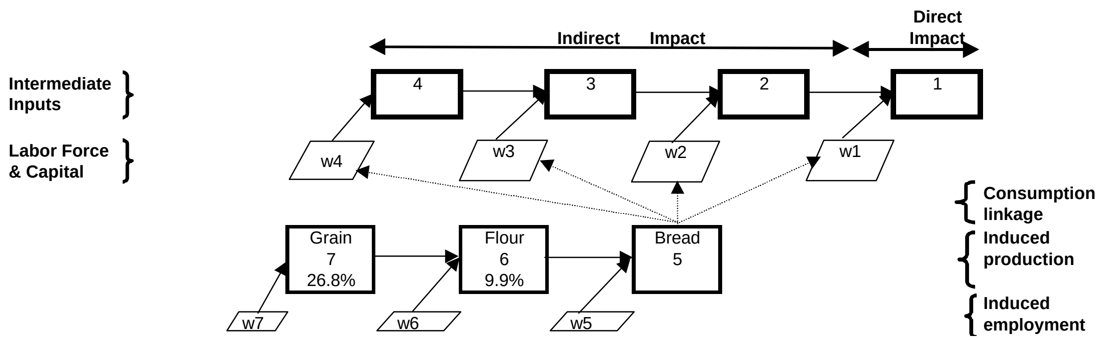

FIGURE 11.4.1-4
THE CHAIN WITH FAMILY EXPENDITURES

The chains of the induced impacts can be extremely important in regions where consumption activity is strong and services are well developed. In such areas, relatively weak direct and indirect impacts may lead to surprisingly high induced impacts. Therefore, it is the sum of all the impacts –direct, indirect, and induced— that is of interest in evaluating the regional effects of the restoration plans.

The actual computation of all the chains and impacts sketched above can be undertaken once the economic character of the region is cast into a statistical framework that specifies the inputs into each activity and the destination of the sales of each activity. The arrangement of data in this form is known as the "input-output table," and information for this table is gathered and reconciled by a number of statistical agencies.[10]

Once the regional accounts are established for the most recent year possible, then the statistical structure may be manipulated to answer the following question: what will be the effect of new major expenditures on the levels of output, earnings, and employment in the region, given the stability of the present economic structure and proportionate relationships between producing sectors? This means that the future economy is likely to look like the present one and that doubling the output of the construction sector, for example, will require a doubling of the current inputs, including the elements of value-added.

---

[10] The Bureau of Economic Analysis (BEA) of the U.S. Department of Commerce is responsible for publishing the US input-output tables. See Ann M. Lawson "Benchmark Input Output Accounts for the US Economy, 1992" in Survey of Current Business, November 1997, pp.36-86, and See Minnesota IMPLAN Group, Inc., IMPLAN Professional: User's Guide, Analysis Guide, Data Guide. Stillwater, MN: 1996, pp. 201-262.

The procedures for analyzing these impacts are now fairly well developed, but considerable care must be exercised in specifying, on as detailed a level as possible, the new activities and their magnitudes. Total construction costs of hundreds of millions of dollars must be disaggregated by the constituent line items and each of these assigned to a producing sector. The total economic impact of a project can then be computed as the sum of the chains triggered by all the intermediate purchases, for example, of concrete, steel rods, pumps, earthmoving, and engineering services, that are required, together with their inputs, the newly added value added, and the production triggered by the workers' spending.

E.11.4.2 The Regional Input-Output Structure

To get acquainted with input-output accounting as well as the characteristics of the South Florida region, the 528 economic sectors of the IMPLAN statistical framework have been aggregated into four major sectors.[11] The contents of each of the four major sectors is given in Table 11.4.2-1.

An aggregated input-output table for South Florida is presented in Table 11.4.2-2. Each vertical column in this table gives the recipe of inputs needed to produce that sector's final sales. Reading across the rows identifies the sector-destinations of those sales.

Inputs are of two types. The first five rows of Table 11.4.2-2 list the "intermediate inputs," the ingredients purchased from other sectors including purchases from other enterprises in the same sector. Thus, the agricultural-mining sector, column [1], purchases $628 million worth of products and services from enterprises within agriculture, row [1], plus $49 million from construction, row [2], $426 million from manufacturing, row [3], and $587 million from services, row [4]. The sum of intermediate inputs is $1.68 billion, given in row [5].

[11] For the reconciliation of the BEA categories with the 528 IMPLAN sectors, see Minnesota IMPLAN, <u>IMPLAN Professional</u>, Appendix A, pp. 269-79. The South Florida table is constructed by applying the sectoral totals for 1995 from the counties in the study area to the technologies given in the most recent national input-output table.

Table 11.4.2-1
The Four Major Sectors of South Florida

4-Sector Aggregation Scheme	528-Sector Aggregation Scheme
1. Agriculture and Mining (A)	47 sectors, including livestock, field crops, sugar crops, fruits and vegetables, greenhouses, landscape services, all mining, sand & phosphate rock quarrying
2. Construction (C)	10 sectors, including new homes, industrial & utility structures, maintenance & repair of structures & wells
3. Manufacturing (M)	375 sectors, including food processing, sugar mills, beverages, cigarettes, textiles, furniture, drugs, metals, motors, machinery, chemicals, vehicles, scientific equipment
4. Services (S)	96 sectors, including transportation, utilities, trade, finance, real estate, personal & business services, auto repair, entertainment & recreation, medical, legal, educational, social services, professional, all levels of government
Total	528 sectors

The second type of input consists of the categories of value-added, which are here grouped into two major portions: wages and salaries, row [6], valued at $1.10 billion, and “other,” row [7], which includes profits, rent, and taxes, valued at $1.27 billion. Total value added, row [8], is thus $2.37 billion. The grand sum of all costs, known as “gross inputs,” row [9], is $4.06 billion. Total employment in the agricultural or “A” sector is 93,100 workers, given in line [10] of column [1].

The sales or deliveries of the products of the agricultural-mining sector are read across the columns of the table. Thus, agriculture, row [1], sells $628 million to itself, $256 million to construction or “C,” column [2], $ 1.66 billion to manufacturing or “M,” column [3], and $ 1.72 billion to services or “S,” column [4]. The value of total sales from one sector (row) to other sectors for further processing is called “intermediate demand,” which, in the case of agriculture, amounts to $ 4.27 billion, shown in row [1] and column [5].

Table 11.4.2-2
South Florida Regional Input-Output Table
1995
(in millions of dollars)

Outputs / Industries → Inputs / Commodities ↓	[1] A	[2] C	[3] M	[4] S	[5] Total Intermediate Demand	[6] Household Expend.	[7] Other Final Demand	[8] Total Final Demand	[9] Total Output
	Intermediate Demand								
[1] Agriculture, Mining (A)	628	256	1,668	1,723	4,275	475	-684	-209	4,066
[2] Construction (C)	49	18	191	3,767	4,025	0	13,265	13,265	17,290
[3] Manufacturing (M)	426	6,059	9,094	9,956	25,534	15,768	-15,635	133	25,667
[4] Services (S)	587	4,066	5,189	42,750	52,592	62,995	64,068	127,063	179,655
[5] Total Intermediate Inputs	1,689	10,399	16,142	58,196	86,426	[79,238]			
[6] Wages & Salaries	1,102	5,008	6,572	66,196	[78,801]				
[7] Other Value Added (profits, rent, taxes)	1,275	1,884	2,953	55,264	61,453				
[8] Total Value Added	2,377	6,892	9,525	121,460				140,254	
[9] Gross Input	4,066	17,290	25,667	179,655					266,679
[10] Employment (1,000)	93.1	198.9	172.9	2,470.0				Sum	2,934.6

Sales to households, government, exports sent outside the region, imports received from outside the region, and sales regarded as investments are all classified as “final demand.” The regional table shown in Figure 11.4.2-2 divides final demand into two categories, “household expenditures,” shown in column [6], and “other final demand,” shown in column [7]. The latter includes all final sales other than to individual consumers. (The negative numbers in rows [1] and [3] of “other final demand” and in row [1] of “total final demand,” column [8], indicate the dominance of imports over all the other categories of final demand. The convention is to treat sales, including exports, as positive numbers which, in these three cases, have been outweighed by the value of imports, which is treated as a negative number.)

The sum of all the costs of “making” products, including profits, must equal the value of the sales of the products. Thus, the column sum of gross inputs purchased by agriculture, which is $4.06 billion, as shown in col. [1], row [9], must equal the value of total sales of A of $4.06 billion, shown in row [1], column [9]. Total intermediate inputs for the four sectors must equal total intermediate demands, that is, $ 86.4 billion, shown in row [5], column [5]. Total value added, which is the sum of all payments to the “factors” of production (labor, capital, land), plus taxes), must equal total final demand, that is, $ 140.2 billion, shown in row [8], column [8]. The value of gross inputs for the entire region equals the value of total output for the region, which is $ 226.67 billion, shown in row [9], column [9]. Total employment is 2.9 million workers, is shown in row [10], column [9].

The sectoral breakdowns –the vertical columns — summarize the fixed “recipes” for producing each sector’s outputs. Doubling final agricultural sales to households, shown in row [1], column [6], for example, requires doubling all the inputs into agriculture, including all the components of value-added and employment. But doubling final sales of agriculture also means doubling the $426 million that A buys from M, shown in column [1], row [3]. This, in turn, means that M must increase its output by a further $426 million, by purchasing more of the inputs according to the “recipe” found in column [3]. The final resolution of all these chains is computed by the mathematical process known as “inverting the input-output matrix,” and once accomplished, the statistical results provide shortcuts in the application to impact analysis.

It should be noted that the traditional definition of the input-output table is specified only by the rows and columns of Intermediate Demand, which is the lightly shaded area in Table 11.4.2-2. (from row [1]/column [1] to row [5]/column [5]). However, the inclusions of wages and salaries, row [6], and of household expenditures, column [6] (i.e., the more darkly shaded area in this table), makes it possible to compute the "induced" impacts of employees' spending within the region.[12]

The internal structure of the economy -who sells to whom and who buys from whom—is thus totally specified for all the sectors of the input-output table. It also gives a clear, analytic breakdown of the importance of each sector in the region in terms of value sold both to final and to intermediate demand. The largest of the four major sectors is services, column [4] and row [4], which purchases a total of $ 58 billion worth of intermediate inputs from other sectors, pays $ 66.2 billion in wages and salaries, and employs 2.47 million workers in the region, more than all the other sectors together! The service sector also dominates sales to households, which total $ 62.99 billion, and sales of $64.06 billion to the other categories of final demand.

E.11.4.3 Purchasing From Inside And Outside The Region

The regional economy is, by its nature, extremely "open" to products purchased from other areas. Regions tend to specialize in certain activities, buying what they need from other regions. Therefore, in evaluating the impacts of a given project on the region, it is helpful to have a measure of its economic "porousness" or "openness." Expenditures of $100 million could cause major ripples within an area or disappear without a trace, depending on the local economic "linkages" that exist between sectors in the region.

The input-output table shown above in Table 11.4.2-2 gives all the flows between sectors, regardless of whether the inputs are imported or locally produced. These "recipes," expressed as fractions of each column, and give the "direct requirements" for each sector, are called "gross absorption coefficients." However, only a portion of each of these ingredients is actually bought within the region, and this local portion is known as the regional purchase coefficient. The resulting share of each item in each column that is bought locally is called the "regional" (as opposed to "gross") absorption coefficient, and it is this fraction that traces the direct impact of new expenditure on the region. How these coefficients function and what can be learned from them will be examined in this section.

---

[12] The first practical computation of this type which "closed" the input-output table by including income and expenditures within the basic matrix was done by R. Weisskoff, "Income Distribution and Export Promotion in Puerto Rico." In Advances in Input-Output Analysis, edited by K. Polenske and J. Skolka. Cambridge, MA: Ballinger Publishers, 1976. pp. 205-228. The computation of the induced impacts was extended to U.S. data by IMPLAN a decade later. On the importance of the inclusion of consumption linkages in improving the accuracy of forecasts, see R. Weisskoff, Factories and Food Stamps: The Puerto Rico Model of Development. Baltimore, MD: Johns Hopkins University Press, 1985, ch. 1-5, and Adam Rose, B. Stevens, and G. Davis, Natural Resource Policy and Income Distribution. Baltimore, MD: Johns Hopkins University Press, 1988, ch. 2 and 4.

The flows of annual expenditures laid out in ***Table 11.4.2-2*** above have been made into percentages, based on the total inputs needed by each of the major sectors, A (for agriculture), C (for construction), M (for manufacturing), and S (for services). These are shown in ***Table 11.4.3-1***.

Table 11.4.3-1
Direct Requirements
Gross Absorption Coefficients
(with no imports)

	A	**C**	**M**	**S**	**HH Exp.**
A	0.154	0.015	.0065	0.010	0.006
C	0.012	0.001	0.007	0.021	0.000
M	0.105	0.350	0.354	0.055	0.199
S	0.144	0.235	0.202	0.238	0.795
Sum Intermediate Demand	0.415	0.601	0.628	0.324	1.000
Value-added	0.585	0.399	0.372	0.676	
Total	1.000	1.000	1.000	1.000	

Where:

A = Agriculture & Mining
C = Construction
M = Manufacturing
S = Services
HH Exp = Household Expenditures

In the agricultural sector, for example, intermediate purchases and value-added are responsible for 41.5% and 58.5%, respectively, of total inputs. In the service sector, by contrast, intermediate purchases and value-added account for 32.4% and 67.6%, respectively, of total inputs. The right-most column in the table, household expenditure, gives the distribution of household expenditure among the sectors: 79.5% is spent on services, which includes rent, utilities, and retail markups, in contrast to 19.9% spent on manufactured goods and 0.6% spent on agriculture.

The high proportion of food, fuel, fertilizer, and manufactures imported by South Florida from other regions is reflected in the regional purchase coefficients shown in ***Table 11.4.3-2***. For example, only 22% of agricultural goods and 19% of manufactures are purchased locally, in contrast to 99% for construction and 84.2% for services.

Table 11.4.3-2
Regional Purchase Coefficients
(share of each sector's intermediate goods bought locally)

Sector	Percent
A	22.1%
C	99.4%
M	19.0%
S	84.2%

The combination of information from the two previous tables provides estimates of the regional absorption coefficients, shown in ***Table 11.4.3-3***. Here, the column fractions give the shares spent locally of each dollar's worth of inputs. In agriculture, for example, 18.8 cents of each total dollar are paid to local intermediate suppliers and 24.9 cents to local workers. This is relatively low compared to the fractions of spending of the service sector that remain in the area – 23.4 cents for local intermediate purchases and 36.8 cents for local compensation.

The distinction between the gross and regional absorption coefficients (***Tables 11.4.3-1*** and ***11.4.3-3***) highlights the difficulty encountered when a region tries to capture the economic linkages normally associated with major sectors. In the case of South Florida, the high degree of "openness" of the agriculture and manufacturing sectors reduces the degree of cohesiveness of the local economy and causes, in effect, a "leakage" or loss of funds to other regions. Florida's growth, in other words, contributes to the prosperity of other regions, and except for the service sector, the region must attract fresh sources of funds to sustain its own growth.

Table 11.4.3-3
Direct Requirements, Net of Imports
Regional Absorption Coefficients

	A	C	M	S	HH Exp.
A	0.034	0.003	0.014	0.002	0.001
C	0.012	0.001	0.007	0.021	0.000
M	0.020	0.067	0.067	0.011	0.038
S	0.122	0.199	0.170	0.200	0.669
Sum	0.188	0.270	0.258	0.234	1.000
Compensation	0.249	0.290	0.256	0.368	
Total Local	0.437	0.560	0.514	0.602	

A summary comparison of the sectoral structure of the region is shown in ***Table 11.4.3-4*** and is based on the rows of the input-output table. Services are shown to dominate the economy, accounting for 79.3% of output, 83.9% of compensation and 84% of regional employment. Manufacturing ranks second in its share of output and earnings but third, behind construction, in employment.

Table 11.4.3-4
Characteristics of the Four Primary Sectors in South Florida

Sector	Share Output	Share Compensation	Share Employment
A	1.8%	1.4%	3.2%
C	7.6%	6.4%	6.8%
M	11.3%	8.3%	5.9%
S	79.3%	83.9%	84.1%
Total	100.0%	100.0%	100.0%

The full regional input-output model for South Florida, with all 528 sectors, will now be utilized to evaluate the impacts of the restoration expenditures.[13]

[13]For other recent studies in the South Florida region, see R.L. Degner, S.D. Moss, and W.D. Mulkey, Economic Impact of Agriculture and Agribusiness in Dade County, Florida. Gainesville: Institute of Food and Agricultural Sciences, August 1997, and D.B.K. English, W. Kriesel, V. R. Leeworthy and P.C. Wilely, The Economic Contribution of Recreating Visitors to the Florida Keys/Key West. NOAA, November 1996.

E.11.5 REGIONAL ECONOMIC IMPACTS

E.11.5.1 Overall Impacts: Output, Jobs, and Earnings

The impact of all the categories of expenditure on gross output (sales), jobs, and earnings were computed for each alternative (***Tables 11.5.1-1***, ***2*** and ***3***). The expenditures responsible for each type of impact were then converted into uniform annual equivalents to account for the degree to which each impact would occur at different periods in the future and for differing lengths of time (***Tables 11.5.1-4, 5***, and ***6***).

For each alternative and for each indicator, three options are presented, depending on the assumptions applying to the output of the agricultural lands. In terms of output (***Table 11.5.1-1***), the impacts range from $ 278.5 million to $ 595.2 million when the foregone production of the EAA lands is subtracted (line G[1]). The impacts range from 0.12% to 0.26% of current total output in the study area. A similar range is found for the impacts on jobs and earnings.

When the impact-causing expenditures are converted into uniform annual equivalent values, then the effects are reduced (***Tables 11.5.1-4, 5,*** and ***6***). The total impacts on output for the medium option in which only EAA sugar output has been considered (line G [1] of ***Table 11.5.1-6***) range from 0.09% to 0.19% of regional output or less than 1/5th of one percent of total study area.

The impacts of the alternative restoration plans appear to be small compared to the total level of economic activity in the project area for a number of reasons. First, the highest level of new construction activity anticipated, for example, in alternative D-13r, is estimated to be $300.7 million per year (from ***Table 11.3.4*** above, line 2A). The normal level of all construction activity in the region, however, has been on the order of $9.0 *billion* per year.[14] The restoration project therefore represents a 3.34% or1/30th addition to the total level of regular construction in the region. In addition, the features of the plan which account for the greatest share of construction and maintenance costs rely heavily on imported materials and on technologies not yet acquired by local manufacturing and construction enterprises.

Despite the small quantitative effects, the restoration project may have significant effects on the region by securing the unique amenities of the area, the benefits of which fall outside the scope of traditional economic impact analysis.

[14] See 1997 Fla. Stat. Abstr., Tables 11.03, 11.15, and 11.20 to assess the share of S. Fl. in the statewide total.

*Note: UAEV represents the conversion of the impacts into an annual equivalent as they are estimated to occur over the 50-year period of analysis, using a discount rate of 6.875%. The factors for UAEV conversion for the various categories of costs are: 0.78872 for lines A & B; 0.57445 for line C; 0.49812 for line D; 1.03380 for line E; and 0.49812 for line F. Differences between the conversion factors for the different categories are due to the timing of the costs and the duration of their impacts.

E.11.5.2 Timing and Persistence of Impacts

Since the total effects of the six categories of impacts occur over different time horizons, the summary effects given in ***Tables 11.5.1-1*** through ***11.5.1-3*** represent the upper limit if all these effects were to occur simultaneously. In reality, the impacts of the construction and real estate purchases (lines A and B) last only as long as those activities are carried out, which is assumed to be 20 years. The impacts of the monitoring and operation-maintenance costs (lines E and F) begin at a relatively low level at the time the project is initiated, rise to a maximum, and then continue at a constant level once the project is completed. The impacts due to the transfer of agricultural land to water storage (line C) begin once the project is initiated and persist throughout the study period.[15] The agricultural gains due to modified water deliveries (line D), however, may be delayed until the project is near completion. The uniform annual equivalent values shown in ***Tables 11.5.1-4*** through ***11.5.1-6*** represent an estimation of the effect of the differences in timing of different impacts, and are generally slightly lower than the impact values in ***Tables 11.5.1-1*** through ***11.5.1-3***.

Moreover, the people who become unemployed will not necessarily be the same people who will be employed as a result of the project for a number of reasons. The skills and needs for new workers associated with construction do not necessarily coincide with those who are being displaced. Nor will the timing of the unemployment necessarily coincide with the timing of the newly employed.

Recent unemployment surveys from the U.S. Bureau of Labor Statistics have found from 87 to 90% of all the unemployed find new jobs within six months.[16]

---

[15] This also represents an upper limit of this impact category, as it assumes that the effect of soil subsidence on crops grown on these lands is offset by the gains in productivity due to improved genetic strains. This may be unlikely, even in view of the reduced rates of subsidence found recently in a sample of five transects taken only in the upper belt of the EAA closest to Lake Okeechobee. See S.F. Shih, B. Glaz, and R.E. Barnes, Jr., Subsidence Lines Revisited in the Everglades Agricultural Area, 1997, IFAS University of Florida Agricultural Experiment Station Bulletin (Tech.) 902 (December 1997). In reviewing other studies and forecasts of subsidence in the EAA, Snyder and Davidson wrote that earlier research had found the historical rates of subsidence predicted in 1951 to be on target as recently as 1988, and that by the year 2000, it was expected that 45% of the soils would be less than one foot thick over the limestone bedrock. "Today," they wrote in 1994, "some farmers are in fact growing sugarcane on soil somewhat less than 1 ft. in thickness over the bedrock, but already areas have been abandoned, and only a few years of conventional production can be expected from such soil." They anticipated that wetland crops or new types of activity would have to be undertaken in the EAA in view of the reduced soil cover. They concluded by asking, "Will millions of dollars be spent creating a method for dealing with today's problem, without considering that agricultural activity in the EAA will likely diminish, or change dramatically, in the future?" See G. H. Snyder and J.M Davidson, "Everglades Agriculture: Past, Present, and Future," Chapter 5, in S. M. Davis and J.C. Ogden, Everglades: the Ecosystem and Its Restoration (Boca Raton, FL: St. Lucie Press, 1994), pp. 108-109. Independently, an economic study of the EAA had estimated that by the year 2013, nearly 81,000 acres of agricultural land would have to shift to other land uses due to an organic soil layer of six inches or less. See Hazen and Sawyer, Twenty Year Evaluation: Economic Impacts from Implementing the Marjory Stoneman Douglas Everglades Restoration Act and the United States versus SFWMD Settlement Agreement. Contract Completion Report. (Hollywood, FL: August 1993), p. 4-17.

[16] U.S. Department of Labor, Bureau of Labor Statistics, Monthly Unemployment Surveys (July 1998), Table A-6, which gives summary results of monthly surveys from July 1997 to July 1998. A study of the effect on the timber industry in Washington and Oregon by the U.S. Department of Interior applied three different reemployment scenarios. It assumed that 92% of the unemployed workers would be reemployed within the first six months and the remaining 8% would be reemployed within the second six months. Alternative assumptions were 80/20 and 70/30 for the fractions employed in the first and second six-month periods. See Depart of Interior, "The Report of the Secretary of the Interior to the Endangered Species Committee Related to the Application by the Bureau of Land Management for Exemption from the Requirements of Section 7(a)(2) of

However, the most recent survey of "displaced" workers, that is, those who lost their jobs due to plant closings, found that three quarters of the long-tenured workers were re-employed within two years, and that one half of these were in jobs earning as much or more than their former ones. One fourth suffered earnings losses of 20 percent or more.[17] The rates of reemployment and the degree of salary recovery vary according to the experience of the workers, occupation, industry, age, sex, and race. Displaced workers may be able to find new employment within the region or migrate to other areas, depending on their skills and the types of new opportunities created in the regional economy.

E.11.5.3 Fiscal Impacts

There are tax implications of the various impacts. These include the additional revenue that will accrue to the state due to new corporate profits from local construction companies (impact category A), the profits of the local companies engaged in monitoring (category E), and the increase in profits of the agricultural corporations due to the gains from modified water deliveries (category G). The spending of the increased earnings of newly employed workers will result in increased local and state sales taxes.

The biggest loss of county revenue may be from the transfer of land from agricultural use to water storage. The most significant block of this type of land is the 60,000-acre tract in the Everglades Agricultural Area in western Palm Beach County. If this block of land were located in the belt currently assessed at $500/acre that is furthest from the lake in the southern-most border of the county, then the county would lose $30 million in taxable land, which represents 4.05% of the total assessed value of agricultural land but only .06 of 1% of the county's total assessed property value.[18] The loss of revenue to the county would be $600,000 per year, calculated at the current ad valorum millage rate of 20, and this represents .04 of 1% of the total revenue of Palm Beach County in 1995.[19] Alternatively, some of this land may be abandoned as the organic soil subsides to a few inches of thickness covering the bedrock. The losses in rural property taxes may also be offset by increases in urban property taxes due to rising employment and increases in revenues from local sales taxes and impact fees.

[Data in this section of the appendix is based on current working estimates available at the time of the regional impact analysis, and hence may not be based on precisely the same cost data being used in the rest of the report; nonetheless, the

results of the impact evaluation and analysis are not expected to differ significantly from analysis based on the latest cost data.]

E.12 OTHER SOCIAL EFFECTS

E.12.1 OVERVIEW

The Other Social Effects (OSE) account considers the effects of alternative plans in areas that are not already contained in the NED and RED accounts. The categories of effects contained within the OSE account include:

- Urban and community impacts,
- Life, health, and safety factors,
- Displacement,
- Long-term productivity, and
- Energy requirements and energy conservation.

The C&SF alternative restoration plans could result in beneficial and adverse OSE within the study area. As is evident throughout this appendix, a variety of positive and adverse NED impacts on water supply (agricultural and urban), recreation, commercial fishing, and commercial navigation are expected to result from Everglades restoration. Similarly, the alternative restoration plans could have positive or adverse OSE impacts on south Florida associated with (1) plan implementation, including land acquisition, project construction, and operations and maintenance (O&M) activities, and (2) operation of the modified C&SF system. As in the case of the NED effects, the OSE account is concerned with the net effects of the alternative plans (i.e., the differences between the with- and without-project future conditions).

Some of the potential OSE impacts would occur primarily at the regional scale, and others would have more localized effects. At both scales, there may be some individuals and communities that are positively affected by Everglades restoration, some that are adversely affected, and many that are not affected at all. Relative to the size of the regional or local economies, the OSE effects may be minimal. However, if these effects occur predominantly within a limited geographic area, or affect a relatively small or vulnerable population, then the impacts can be disproportionately large. Therefore, the purposes of OSE analysis include not only determining the total magnitude of potential impacts, but also identifying the population (and its characteristics) which would be affected by any proposed action.

Some of the categories of effects typically included in the OSE account do not pertain to the alternative restoration plans. For example, the alternative plans are not expected to affect energy use or energy conservation in the study area. As will be noted, other categories of potential OSE impacts have been addressed previously in this appendix.

E.12.2 POTENTIAL URBAN AND COMMUNITY IMPACTS

Urban and community impacts is the principal category of potential OSE impacts associated with the alternative restoration plans. This category of impacts includes effects on income distribution, employment distribution, population distribution and composition, and quality of community life. Some urban and community impacts have previously been addressed in this appendix. For example, regional income effects and fiscal impacts were discussed in the Regional Economic Development analysis (Chapter 11). In addition, the impacts of agricultural water supply and municipal and industrial water supply were discussed in detail in Chapters 4 and 5, respectively.

The OSE assessment of urban and community impacts considers both the potential for exposure to the effects of the alternative restoration plans and the degree of vulnerability to potential impacts. Exposure refers to whether an individual or community is subject to the other social effects of the alternative plans. Vulnerability refers to the ability of that individual or community to respond or adjust to those effects.

Potential urban and community impacts of the alternative restoration plans could result from: (1) land acquisition and potential relocation of populations for reservoir and other project construction features, (2) reduced agricultural activity associated with taking the reservoir lands out of cultivation, and (3) construction activity associated with plan implementation. In general, construction activity is considered to have positive impacts. At the local scale, construction and O&M activities associated with the alternative restoration plans can have positive effects to local residents and communities by providing jobs, increasing local wages, increasing local sales, increasing tax revenues and generally benefiting the local economy.

Among the largest construction activities and land purchases associated with the alternative restoration plans are new reservoirs that are intended to add storage to the C&SF system. The proposed locations of these multiple storage facilities have not yet been established, but potential locations include the Everglades Agricultural Area, the Caloosahatchee and St. Lucie basins, and the Kissimmee Basin. The availability of contiguous parcels of low intensity, agricultural land is one of the most important economic considerations in locating these reservoirs. A real estate analysis will be conducted during the next phase of study to determine the exact location of the storage facilities.

Lands associated with new reservoirs will be purchased from existing property owners who will be paid fair market value and will qualify for relocation assistance payments under the guidelines established by PL 91-646, The Uniform Relocation Assistance and Real Property Acquisition Policy Act of 1970. The OSE effects of population displacement cannot be estimated until the detailed design phase, when the magnitude of land purchases, and the number and characteristics of affected landowners are determined. During this phase, property owners will be contacted by real estate personnel to determine their willingness to sell. Negotiations will commence with willing sellers. If the property owner is unwilling to sell, or if a negotiated price cannot be reached, the government may choose to exercise its power to acquire lands by eminent domain. The results of these negotiations will also influence the extent and severity of OSE effects on displaced populations.

The effects of the land purchases may also not be confined solely to the land owners. Because the Federal government is not subject to local real estate taxes, transfer of land title from private to public ownership often results in tax revenue losses to local jurisdictions, unless payments in lieu of taxes are provided. Land values in surrounding areas may also be affected by speculation in anticipation of project implementation, and real estate taxes can be affected by changes in property values.

Regardless of the impacts on the land owners, when agricultural land is taken out of production, the associated farm labor (resident and migrant) may lose their jobs, and the local economy and community can be adversely affected by the decrease in agriculture-related spending. In many rural areas of south Florida, agriculture provides the economic foundation for local economies and community life. The economic resilience and social cohesion of affected families and communities determine the severity and duration of the effects of the conversion of farm land to reservoirs.

Job loss can cause lowered self image, depression, and anger. Subsequent adverse social effects can often follow. Agricultural communities are not immune to the economic fluctuations of farm economies arising from weather, pests, price fluctuations, and foreign competition. However, when adversity is attributed to government decisions, resentment often replaces resolve and communities can be further strained by a sense of abandonment.

The low population densities in the rural areas of south Florida suggest that it is unlikely that the conversion of farm land to reservoirs would create major population displacements. In addition, the low labor intensity of agriculture in the areas under consideration for reservoir siting (e.g., sugar cane and citrus) indicate that the employment effects may also be small. However, many of the communities in these rural areas are small and dependent on agriculture for their prosperity. If a significant percentage of local farm land is converted to a reservoir, the impacts on those communities could be very significant.

There are a variety of social and economic factors that are important determinants of an individual's or community's ability to cope with adversity. One of the most important economic factors in the ability of individuals and groups to respond is the number of employment alternatives available locally. The ability to find another job depends on the education and training of the work force as well as the needs of local economic concerns, such as other farms, agricultural-related services, or some other local business. The socio-economic makeup of the community is also an important consideration of the ability of individuals and the community at large to cope with the adverse effects of large-scale agricultural land conversion. Some groups in society are recognized as having less opportunity to respond to adversity. These groups include ethnic and racial minorities, the elderly, and the poor. Table 12.2-1 presents a socio-economic vulnerability profile for each of the study area counties. This profile contains information that indicates the ability of the county population to respond to social and economic adversity. It is important to recognize that the county scale may not accurately reflect the ability of any given community or groups within a community to accommodate potential changes associated with the alternative restoration plans. More detailed studies of individual communities is not warranted until the potential reservoirs have been sited.

Table 12.2-1 contains the racial/ethnic mix of each of the study area counties, as well as population over 65 years of age, 1990 unemployment, per capita income, and the expected changes in employment and income from 1990 to 2010. While this table contains all of the study area counties, those counties which are potential locations of new reservoirs include:

- Palm Beach County (Everglades Agricultural Area),
- Lee County (Caloosahatchee Basin),
- Martin County (St. Lucie Basin), and
- Highlands, Osceola, Orange, Polk, and Okeechobee counties (Kissimmee Basin).

The study area counties have a wide range of ethnic compositions, proportions of elderly population, unemployment rates, and per capita incomes. In general, the rural counties in the study area, such as Hendry and Okeechobee, have relatively high levels of unemployment, low per capita incomes, high levels of poverty, and slow growth in employment and income. These socio-economic characteristics suggest that the rural counties of the study area – those that are expected to provide locations for new storage reservoirs – are areas that are least able to accommodate the associated economic and social effects on local communities. However, in these rural areas the affected populations should be relatively small.

Although the restoration of the Everglades ecosystems is a unique undertaking, there have been other projects and programs with similar goals and socio-economic contexts. One study conducted by the U.S. Department of the Interior assessed the national and regional economic impacts of not allowing timber harvests in certain old-growth forests in Oregon in order to protect the Northern Spotted Owl. One aspect of this study investigated the re-employment of timber workers who had been displaced by the cessation of local logging activities. Surveys of displaced loggers suggested that they found that 57% of displaced workers reported post-displacement wages equal to or above their previous wages. According to the Bureau of Labor Statistics, 92% of displaced workers find new jobs within one year, and the remaining 8% find jobs within two years.

TABLE 12.2-1
SOCIO-ECONOMIC VULNERABILITY PROFILE

County	White	Black	American Indian	Hispanic*	Other	Population Over 65	Unemployment Rate (1990)	Anticipated Annual Change in Employment (1990-2010)	1990 Per Capita Income**	Anticipated Annual Change in Income (1990-2010)	Percent of Population Below Poverty Level

E.12.3 ADDITIONAL CONSIDERATIONS

The OSE also includes potential impacts on life, health, and safety. Most of these concerns have been addressed previously in this appendix in Chapter 5 (municipal and industrial water supply) and in Chapter 6 (flooding). However, in particular, the OSE can include the potential risks to life, property, and public services associated with structural failure of project elements. Perhaps the most significant concerns regard structural failure of the Herbert Hoover levee system around Lake Okeechobee. It is anticipated that the alternative restoration plans represent significant improvements over the without-project future conditions. Although the regulation schedule for the lake is assumed to be the same under the with- and without-project future conditions, the alternative restoration plans are expected to result in fewer high water events on the lake, thereby reducing the potential for the levee to experience a catastrophic structural failure.

The OSE account also includes issues of long-term economic productivity. As discussed in Chapter 4 (agricultural water supply), the alternative restoration plans should result in significant increases in long-term agricultural productivity by increasing water supplies available to farmers in the Everglades Agricultural Area and the Lower East Coast. The reduction in the frequency of agricultural drought conditions in south Florida will promote long-term productivity by limiting adverse effects associated with soil desiccation, especially in the EAA. These effects include muck fires and soil subsidence.

E.13 SUMMARY OF SOCIO-ECONOMIC EFFECTS

Congress authorized the U.S. Army Corps of Engineers (Corps) and its local partner, the South Florida Water Management District (SFWMD) to conduct the C&SF Project Comprehensive Review Study (Restudy) to develop a comprehensive plan for the purpose of restoring, preserving, and protecting the south Florida ecosystem, as well as meeting other water resource planning objectives such as water supply, water quality, and flood control. This appendix has assessed the economic effects of the five alternative ecosystem restoration plans formulated in the feasibility phase of the Restudy (Alternatives A-D, and the Recommended Plan). The economic evaluation of the alternative restoration plans has included the following elements distributed over 12 chapters. Each of these elements are discussed below.

- Socio-economic profile of the study area,
- National Economic Development (NED) effects of alternative plans,
- NED costs of alternative plans,
- Regional economic development (RED) effects, and
- Other social effects (OSE).

E.13.1 SOCIO-ECONOMIC PROFILE OF THE STUDY AREA

The socio-economic profile of the study area is a compilation of current and projected socio-economic information on the study area, including race, income, employment, age, and poverty. As described in Chapter 2, this profile serves three important functions. First, it supports the description of the study area. Second, the demographic and economic forecasts for the study area are critical determinants of future water use in the region. The water demands of urban areas in south Florida are an important factor in formulating the alternative restoration plans. Third, the socio-economic profile supports the Other Social Effects (OSE) analysis which considers, among other factors, the resilience of local economies and the cohesion of local communities in determining the social and economic impacts of the alternative plans.

The socio-economic profile of the study area describes a diverse region that includes urban and rural areas, wealthy and poor communities, and commercial and agricultural economies. The diversity has particular relevance for the OSE analysis, since it suggests different abilities of local communities to respond to the potential adverse or beneficial effects associated with implementation of the alternative restoration plans.

As described in Chapter 3, population growth is expected to increase urban water demands in south Florida, particularly in the Lower East Coast (LEC). The expected population growth has relevance for the Restudy, because the projections of increased water demands form important without-project conditions that are incorporated in the South Florida Water Management Model (SFWMM), the principal analytical tool of the Restudy. The extent to which expected population growth translates into new urban water demands also depends on the adoption of water-saving devices and attitudes towards water conservation and water use. To account for the uncertainty underlying population growth and water consumption patterns, several scenarios were included in the forecasts of future study area water demands.

E.13.2 NED EFFECTS OF THE ALTERNATIVE PLANS

The alternative restoration plans have been designed with the goal of restoring the Everglades ecosystems and meeting other water resource planning goals and objectives. The physical and operational changes to the regional water management system proposed to accomplish this goal could potentially have positive or adverse effects on other water-dependent activities in south Florida, including: agricultural and urban water supply, flooding, commercial navigation, recreation, and commercial and recreational fishing. Each of these impact categories is the subject of a separate chapter in this appendix. The results of these analyses are encapsulated in Table 13.2-1, and the potential positive and adverse NED effects of the alternative plans are summarized below.

E.13.2.1 Agricultural Water Supply

As described in Chapter 4, the potential effects of the alternative restoration plans on agricultural water supply are based on the magnitude and frequency of irrigation water shortages. If crops do not receive sufficient moisture from precipitation or irrigation, crop transpiration is reduced, and growth rates can be affected. Reduced growth rates result in lower crop yields and, ultimately, lower farm income. The economic effects of the alternative plans are the differences between expected farm income under the with- and without-project conditions.

The NED account includes the net farm income effects associated with changes in revenues or production costs resulting from plan implementation. The SFWMD has developed an economic post-processor (EPP) to assess the economic effects of agricultural water supply shortages. The EPP, which is embedded in the SFWMM, was used to estimate the value of unmet agricultural water demand in the LEC and the Everglades Agricultural Area (EAA) for the with- and without-project future conditions. ***Table 13.2-1*** presents the values of unmet agricultural water demand for the 2050 without-project (base) condition, the four alternative plans, and the recommended plan.

TABLE 13.2-1
SUMMARY OF ECONOMIC EFFECTS OF ALTERNATIVE RESTORATION PLANS
(all dollar values in $ millions)

IMPACT CATEGORY	WITH- AND WITHOUT-PROJECT CONDITIONS					
	2050 Base Condition	Alternative A	Alternative B	Alternative C	Alternative D	Recommended Plan
NED EFFECTS						
Agricultural Water Supply: Avg. annual value of unmet demand*	$2.6	$0.6 (+$2.0)	$0.9 (+$1.7)	$0.7 (+$1.9)	$0.8 (+$1.8)	$0.7 (+$1.9)
M&I Water Supply: Avg. annual value of unmet demand*	$31.8	$10.2 (+$21.7)	$10.3 (+$21.5)	$6.4 (+$25.4)	$4.6 (+$27.2)	$4.6 (+$27.2)
Flood Control	• Limited evaluation of impacts, since SFWMM not designed for flood studies.					
Commercial Navigation	• No significant difference expected between with- and without-project conditions.					
Recreation	• Problematic to quantify effects of alternative plans. • Current Expenditures: $404 million (parks/preserves); $598 million (region). • Current Consumer Surplus: $290 million (parks/preserves); $764 million (region).					
Commercial/Recreational Fishing	• Annual revenues estimated for commercial and guided & recreational sportfishing in five areas: Lake Okeechobee, St. Lucie & Caloosahatchee estuaries, and Biscayne & Florida bays. • Significant positive economic impacts are expected to result from hydrologic modifications and consequent ecological impacts to all five areas with the exception of Biscayne Bay.					
NED COSTS						
Total Construction & Real Estate Costs		$5,229	$6,023	$6,725	$7,335	$7,820
Annual Operations & Maintenance Costs**		$70	$72	$126	$162	$173
Annual Monitoring Costs		$10	$10	$10	$10	$10
Annualized Costs (6.875% interest rate)		$251	$284	$338	$380	$404
REGIONAL EFFECTS						
Average annual effects (% of regional economy)						
Output		$169 (.07%)	$191 (.08%)	$187 (.08%)	$272 (.12%)	$301 (.13%)
Employment (jobs)		1,689 (.06%)	1,894 (.06%)	2,009 (.07%)	2,849 (.10%)	3,109 (.11%)
Earnings		$58 (.07%)	$64 (.08%)	$77 (.10%)	$101 (.13%)	$107 (.14%)
OTHER SOCIAL EFFECTS	• Potential community disruption from conversion of agricultural land to reservoirs.					

* A "+" indicates a reduction in unmet water demand; i.e., these are benefits.
** Fully constructed

The values in the table represent simulated income losses from agricultural water supply shortages during the SFWMM's 31-year simulation period. The numbers in the parentheses reflect the differences between the with- and without-project future conditions. For each of the alternative plans, the differences are positive, indicating that the alternative plans are expected to improve agricultural water supply in the EAA and LEC relative to the without-project condition. These improvements would be attributed to physical improvements to the C&SF system, such as adding storage capacity via new reservoirs and through more effective management of the regional water system. As indicated in the table, Alternative A is expected to have the greatest reduction in unmet agricultural water demand.

The Caloosahatchee River and the St. Lucie Canal serve as major outlets for Lake Okeechobee, connecting the lake to the Gulf of Mexico and the Atlantic Ocean, respectively. There is significant agricultural activity in the these basins. The EPP does not address agricultural water supply effects in these basins, since they are not included in the SFWMM's grid system. However, the SFWMM simulates the agricultural demands not met for these basins under the with- and without-project conditions. The comparison of these simulations suggests that all of the alternative restoration plans would significantly improve agricultural water supply in the Caloosahatchee and St. Lucie basins. Alternative D (and the Recommended Plan) are expected to have the best performance among the alternative with regard to agricultural water supply in both basins.

E.13.2.2 Municipal And Industrial Water Supply

As discussed in Chapter 5, the alternative restoration plans could also result in changes in the frequency, severity, duration, and location of municipal and industrial (M&I) water supply shortages. In the study area, most M&I water use is in the LEC. When water demands exceed supplies, shortages result, and cutbacks may be imposed by the SFWMD. The SFWMD's Water Shortage Plan curtails water use in south Florida using a four-phase program of progressively more severe restrictions.

The EPP estimates the value of unmet M&I water demand using the results of a survey of LEC water customers. This survey asked respondent's willingness to pay (WTP) for water not received during shortages. The economic impacts of the alternative plans are the differences between the with- and without-project costs associated with the alternative regulation schedules. ***Table 13.2-1*** presents the economic value of unmet demand for M&I water supply for the with- and without-project future conditions. As for agricultural water supply, the M&I numbers in this table that are in parentheses represent the differences between the with- and without-project conditions. Again, the positive numbers in parentheses suggest that the alternative plans would represent significant improvements in M&I water supply which could result from physical and operational improvements to the regional water system. Alternative D and the Recommended Plan are expected to result in the greatest reduction in unmet M&I water demand.

E.13.2.3 Flood Control

As described in Chapter 6, structural and operational changes to the regional water system resulting from the alternative plans could alter the frequency of flooding in some parts of south Florida. Studies to estimate the flooding implications of the alternative plans were limited by the spatial resolution of the SFWMM. This model was not designed for flood studies, and the relatively coarse spatial resolution of this regional model limits its utility in assessing the flood impacts of the alternative restoration plans. Recognizing these limitations, the flooding studies conducted for the Restudy employed a four-part methodology. First, using secondary information and professional judgement, flood problem areas in the region were identified. Second, the SFWMM was used to assess whether these areas would be expected to have higher or lower peak stages as a result of the implementation of the alternative plans. Third, other areas with potential adverse and beneficial effects from the alternative plans were identified. Finally, for those existing problem areas that are expected to be adversely affected, further studies were recommended.

E.13.2.4 Commercial Navigation

As discussed in Chapter 7, the alternative regulation schedules are expected to alter average lake stages on Lake Okeechobee, which is a critical link in the Lake Okeechobee Waterway connecting the Atlantic Ocean with the Gulf of Mexico via the Caloosahatchee River and the St. Lucie Canal. The waterway includes 154 miles of navigation channels and five lock structures. There are two navigation channels through Lake Okeechobee. Route 1, which cuts across the lake, has a deeper channel (8 feet). Route 2, which hugs the eastern shoreline, is known as the rim canal. The channel depths of 8 feet and 6 feet for the lake and rim channel, respectively, are measured relative to an average lake elevation of 12.56 feet NGVD. The channel depths vary with lake levels, and no dredging is performed on this waterway. If the alternative restoration plans affect the frequency of extremely low lake levels (i.e., less than 13 feet NGVD), commercial navigation could be impacted and result in delays, load reductions, or re-routing of commercial traffic.

There has been a small but relatively stable level of commercial navigation on this waterway over the past ten years. The Lake Okeechobee Waterway was used to transport 430,000 tons of freight in 1995. There are no commercial shipping lines which maintain regular service through the Lake Okeechobee waterway. As a result, there is no dedicated fleet of commercial waterway users, and there is no regularly scheduled routing of commodity shipments through the waterway. The commercial traffic consists of special barge shipments that take advantage of the shortcut across the peninsula, which can save 3 to 5 days of travel.

Based upon field research and database searches regarding commercial navigation on the Lake Okeechobee Waterway, it can be concluded that the effects of the alternative restoration plans on the NED account would be very small. All of the alternative restoration plans are expected to lead to significant reductions in the frequency of low lake stages. However, the economic effects of these improvements for commercial navigation are expected to be small.

E.13.2.5 Recreation

As described in Chapter 8, tourism is Florida's largest industry. Many visitors come to enjoy the state's recreation amenities, joining the thousands of Florida residents who are also taking advantage of the State's diverse recreation resources. Many Florida residents and visitors recreate in the Everglades-related recreation resources of south Florida, including Everglades National Park, Biscayne National Park, Big Cypress National Preserve, the Loxahatchee National Wildlife Refuge, and Lake Okeechobee.

The economic value of resource-based recreation is determined by the users' willingness to pay for a recreation occasion. The willingness of current and potential users to pay for resource-based recreation of specific quantity and quality constitutes the demand for that type of recreation. The interaction of demand with the quantity and quality of recreation resources available determines the recreation use or "participation" levels for that resource-based activity. When the quantity or quality of recreation resources is modified by a project, such as the alternative restoration plans, the change in value of resource-based recreation is based on the difference in the willingness of users to pay under the with- and without-project conditions.

The restoration of the Everglades ecosystems could potentially have significant impacts on the value of outdoor recreation in south Florida. The hydrologic changes associated with the Restudy's alternative restoration plans have been designed to improve the structure and function of the Everglades ecosystems. These improvements can be expected to result in increases in the quantity and quality of Everglades-related recreation resources. If the alternative restoration plans improve the ecology of the Everglades, the quality of the Everglades-related recreation and/or the number of people who participate in Everglades-related recreation could increase significantly. Consequently, the value of outdoor recreation in south Florida could increase as well.

As noted in Table 13.2-1, estimating the future value of Everglades-related recreation in south Florida is problematic, and anticipating the incremental changes in value associated with Everglades restoration is even more challenging. There are four principal uncertainties which limit the ability to anticipate the future quantity and quality of outdoor recreation under with- and without project conditions:

- Timing and character of the ecological changes from restoration: If the results of the restoration effort can not be predicted, secondary effects on recreation are even more uncertain.

- Marketing of tourism and Everglades-related recreation: Tourism is particularly sensitive to marketing efforts. Restoration may or may not be accompanied by promotion of the enhanced recreation opportunities.

- Development of recreational facilities and recreational access: Facilities and access are critical determinants of recreation participation. Restoration may or may not be accompanied by development of additional recreation facilities and access.

- Macroeconomic factors which influence tourism and recreation demand: National economic and social trends can greatly influence patterns of tourism and recreation. The uncertainty of these factors limits the ability to forecast tourism and recreation with confidence for more than a few years.

Given these uncertainties, it is beyond the scope of this analysis to quantify the value of Everglades-related recreation under the with- and without-project future conditions through the 50-year planning period. However, the alternative plan that is expected to be most effective in terms of restoration can be expected to also be most effective in terms of positive recreation effects. As indicated in ***Table 13.2-1***, current expenditures and consumer surplus were estimated for Everglades-related recreation in order to help frame the issues surrounding the recreation effects of the alternative restoration plans. There are approximately 6.3 million visitors annually to the principal Everglades parks and preserves. At the regional scale, there are approximately 16.6 million wildlife watching participants in south Florida. It is estimated that the current annual expenditures associated with visitation to the Everglades parks and preserves is approximately $404 million, and expenditures for wildlife watching in south Florida are approximately $598 million. In addition, it is estimated that the annual consumer surplus associated with visiting the parks and preserves is approximately $290 million, and the consumer surplus associated with wildlife watching in the region is $764 million. These estimates of expenditures and consumer surplus, which are based on secondary sources of information, provide insight to the value of the Everglades-related recreation resources, but they should not be interpreted as estimates of that value.

E.13.2.6 Commercial And Recreational Fishing

As explored in Chapter 9, the alternative plans have the potential to affect recreational and commercial fishing throughout south Florida by modifying the hydrologic regime in the region's waterways and estuaries. There are five principal fishing impact zones that would experience the majority of the potential economic effects on fishing in the region: Lake Okeechobee, the Caloosahatchee and St. Lucie estuaries, and Biscayne and Florida bays.

In this investigation, both recreational fishing and commercial fishing are discussed, including recreational sportfishing, guided sportfishing, and commercial fishing. The hydrologic changes that are expected to result from the alternative restoration plans may have economic implications for commercial and recreational fishing in the five impact zones. Economic effects on commercial fishing are estimated based on a net income approach. Increases or decreases in the net income of commercial fishermen can result from either changes in the size of the catch (i.e., revenues) or from changes in the cost of fishing operations (i.e., expenses). For recreational fishing, economic effects are measured based on changes in both the quality of the fishing experience, as well as changes in the frequency of fishing in a given area (e.g., number of fish caught per trip, number of trips, number of fishermen, or hours fished per trip).

Lake Okeechobee supports extensive commercial, guided sportfishing, and recreational sportfisheries. The annual revenues associated with the commercial fishery are estimated at $2.3 million, and spending associated with recreational sportfishing is approximately $700,000. The alternative restoration plans are expected to have positive effects on commercial and recreational fishing by moderating the extent and duration of extreme lake stage fluctuations. This could improve the habitat quality of the lake's littoral zone, which provides important habitat for the lake's commercial and recreational fish stocks. The commercial fishery is not expected to benefit significantly from this effect however, since neither the size of the catch nor the cost of the catch are expected to change. The recreational fishery might marginally benefit from the anticipated habitat improvements, but the sportfishery is already quite healthy and therefore relatively insensitive to the magnitude of the expected hydrologic and ecological changes.

Commercial fishing and guided sportfishing in the St. Lucie estuary have annual revenues of approximately $1.7 million and $800,000, respectively. In the Caloosahatchee estuary, commercial fishing and guided sportfishing have annual revenues of approximately $ 1.7 million and $4.8 million, respectively. Both estuaries receive water released from Lake Okeechobee. The lake is managed to keep lake levels low in the wet season to provide flood protection and high in the dry season for water supply purposes. The quantity, quality, and timing of the releases to the St. Lucie and Caloosahatchee estuaries are critical determinants of the diversity and productivity of those ecosystems. The ecological conditions have implications for commercial and recreational fishing in these estuaries.

There has been long-standing concern about the effects of regulatory releases on the St. Lucie and Caloosahatchee estuaries. Some aspects of the relationship between the regulatory releases and effects on fishing are relatively clear. In general, these estuarine ecosystems are stressed by the magnified oscillations in freshwater inputs to the estuary and other ecosystem perturbations. The stressors include the Lake Okeechobee releases and other influences from the estuary's contributing watershed. The variability in freshwater inputs to the Caloosahatchee Estuary creates an unstable salinity environment.

There is a great deal of uncertainty regarding the effects of the freshwater releases from Lake Okeechobee on these estuaries. These ecological uncertainties translate into uncertainties regarding the economic effects of the alternative restoration plans on commercial and recreational fishing. As indicated in Table 13.2-1, for both of these estuaries, the alternative restoration plans are expected to result in significant improvements over the without-project future condition. However, in the St. Lucie estuary, the alternative plans are not expected to meet the performance targets established for high water releases from Lake Okeechobee. For the St. Lucie and Caloosahatchee estuaries, the alternatives that are expected to have the best performance in terms of high water releases to the estuaries are Alternatives D and B, respectively.

For commercial and recreational fishing in Biscayne Bay and Florida Bay, the sequence of effects of the alternative restoration plans also depends on how the hydrologic changes affect the ecology of the bays and how the ecological changes translate into changes in commercial and recreational fishing. However, the bays have several important differences relative to the St. Lucie and Caloosahatchee estuaries. First, the bays lie at the downstream terminuses of the C&SF system where water flowing through the Everglades enters the sea. Second, the bays, which primarily lie within the Biscayne National Park and Everglades National Park, are recognized as estuaries of national and international significance. Third, the bays are much larger than the St. Lucie and Caloosahatchee estuaries. As a result, they play a much more significant role in south Florida's commercial and recreational fishing.

The quantity and timing of freshwater flows into Biscayne and Florida bays are critical determinants of the structure and function of the bay ecosystems. The bays differ from the two smaller estuaries, since they do not experience the magnified fluctuations of high and low freshwater inputs and resultant salinity levels. Instead, the bays in general receive less water throughout the year than they would under natural conditions.

The bays support significant commercial and recreational fisheries. Biscayne Bay is estimated to have the following annual revenues associated with its fisheries: commercial fishing ($1.5 million), guided sportfishing ($1.4 million), and recreational sportfishing ($8.5 million). Similarly, Florida Bay fisheries have the following estimated annual revenues: commercial fishing ($10.8 million), guided sportfishing ($1.0 million), and recreational sportfishing ($7.0 million).

In general, the with- and without-project future conditions in Biscayne Bay are expected to have freshwater inputs to the bay that fall short for the target discharges (wet and dry seasons). In addition, three of the alternative restoration plans are expected to have less desirable performance than the without-project conditions. The exception is Alternative D. The potential shortfall of the with- and without-project conditions relative to the targets for freshwater inputs to Biscayne Bay suggest a continued salinity stress on the bay ecosystem. This stress may have ecological effects that infer economic consequences for commercial and recreational fishing in the bay. The relatively stable abundance in recent years of economically valuable species suggests that the ecosystem has some resilience to the continued salinity stress from low freshwater inputs relative to historic levels. However, the sustainability of this abundance under continued stress is not known.

To analyze the effects of the with- and without-project conditions on the ecological health of Florida Bay, the SFWMM simulates freshwater inputs to the bay at four different discharge points. The benchmarks for these discharges are the flows that were simulated in the Natural System Model (NSM). As indicated in ***Table 13.2-1***, the alternative restoration plans are, in general, expected to exceed the without-project conditions, and in some cases meet or exceed NSM flows into the bay. While the hydrologic performance of the individual restoration plans are mixed, it appears that for most of the hydrologic measures, Alternative A is superior to the other restoration plans and to the future without-project conditions. The Recommended Plan is expected to produce effects equivalent to Alternative D.

E.13.3 NED COSTS

Chapter 10 describes the NED costs of the alternative restoration plans. As outlined in ***Table 13.2-1***, these costs include construction and real estate, operations and maintenance, and monitoring costs. The average annual costs for Alternatives A, B, C, and D range from $254 million to $383 million. The estimate of average annual costs for the Recommended Plan is $402 million. This estimate is not comparable to the estimates for Alternatives A-D, since it includes other plan elements, developed as part of the refinement of the Recommended Plan.

E.13.4 REGIONAL ECONOMIC EFFECTS

In Chapter 11, the effects of the alternative restoration plans on the regional economic development (RED) account were evaluated using a regional input-output model, IMPLAN. The analysis considered the primary and secondary consequences of the proposed structural and operational modifications of the regional water management system. Primary consequences include the economic activities stimulated by the purchases of materials and services required in the construction of the project, the purchases of real estate, operation and maintenance of the system and monitoring costs. Secondary consequences, such as the NED effects of the alternative plans were also evaluated, specifically the consequences of changing agricultural land use and of changing agricultural water supply.

The types of economic impacts that a new project can have on output, earnings, and jobs in a region are known as “direct,” “indirect,” and “induced.” Direct impacts are caused by first round of expenditures associated with the project. The indirect impacts count only the inputs which are purchased as a result of the first round expenditures. The importance of these “indirect” effects will vary with the complexity of production in the study area and the degree to which required materials are supplied by local producers. Induced effects are the multiplier effects of the project expenditures as that spending circulates in the regional economy.

Table 13.2-1 summarizes the regional economic development effects of the alternative plans. These effects are categorized as changes in output, employment, and earnings. They estimates for each of the alternative plans are presented in absolute terms for the 50-year period of analysis and as a percentage of the regional economy. As expected, the regional effects of the alternative plans generally increase from Alternative A to the Recommended Plan in accordance with the increasing expenditures associated with each plan.

E.13.5 OTHER SOCIAL EFFECTS

As discussed in Chapter 12, the C&SF alternative restoration plans could have socio-economic effects on the study area that are not identified in the national economic development (NED) account or in the regional economic development (RED) account. The Other Social Effects (OSE) account provides the opportunity to display and integrate into water resources planning information on plan effects from perspectives that are not reflected in the NED and RED accounts. The categories of effects in the OSE account include:

- Urban and community impacts,
- Life, health, and safety factors,
- Displacement,

- Long-term productivity, and

- Energy requirements and energy conservation.

As in the case of the NED effects, the OSE account is concerned only with the effects of the alternative plans (i.e., the differences between the with- and without-project future conditions). The most potentially significant OSE consideration for the alternative restoration plans concerns the development of new storage reservoirs in the rural areas surrounding Lake Okeechobee. These project features would convert farm land to reservoirs. Their development could eliminate the jobs of the individuals who depend on those lands for their employment and have adverse effects on local communities and economies. The potential locations of the new reservoirs are not known at this time. However, the resilience of local economies and the cohesion of local communities to agricultural land conversion depend on a variety of factors, including the age, ethnic, and racial composition of the community and income, unemployment, and poverty levels. A social vulnerability index was developed using county-scale socio-economic characteristics, and this type of analysis could be replicated in more detail when and if new reservoir sites are proposed.

APPENDIX F
REAL ESTATE

F.1 PURPOSE

The purpose of the Comprehensive Review Study is to determine the feasibility of modifications to the Central and Southern Florida (C&SF) Project to restore the Everglades and Florida Bay ecosystems while providing for other water-related needs. The C&SF Project is a multi-purpose project. It provides flood control and water supply benefits to the people of south Florida, while allowing for water control, preventing salinity intrusion, providing navigation, preservation of fish and wildlife, and providing water to the Everglades National Park.

This Real Estate Appendix addresses the real estate requirements for the alternative plans and elements considered in the feasibility phase review study. This appendix is tentative in nature for planning purposes only and the real estate cost estimates provided are subject to change even after approval of the feasibility report.

F.2 AUTHORITY

This study is authorized by Section 309(l) of the Water Resources Development Act of 1992 (Public Law 102-580) which states:

> *(1) CENTRAL AND SOUTHERN FLORIDA. -- The Chief of Engineers shall review the report of the Chief of Engineers on central and southern Florida, published as House document 643; 80th Congress, 2nd Session, and other pertinent reports, with a view to determining whether modifications to the existing project are advisable at the present time due to significantly changed physical, biological, demographic, or economic conditions, with particular reference to modifying the project or its operation for improving the quality of the environment, improving protection of the aquifer, and improving the integrity, capability, and conservation of urban water supplies affected by the project or its operation.*

This study is also authorized by two resolutions of the Committee on Public Works and Transportation, United States House of Representatives, dated September 24, 1992. The first resolution states:

> *Resolved by the Committee on Public Works and Transportation of the United States House of Representatives, That the Board of Engineers for*

Rivers and Harbors, is requested to review the report of the Chief of Engineers on Central and Southern Florida, published as House Document 643, Eightieth Congress, Second Session, and other pertinent reports, to determine whether modifications of the recommendations contained therein are advisable at the present time, in the interest of environmental quality, water supply and other purposes.

The second resolution states:

Resolved by the Committee on Public Works and Transportation of the United States House of Representatives, That the Board of Engineers for Rivers and Harbors, is requested to review the report of the Chief of Engineers on Central and Southern Florida, published as House Document 643, Eightieth Congress, Second Session, and other pertinent reports, to determine whether modifications of the recommendations contained therein are advisable at the present time, in the interest of environmental quality, water supply and other purposes for Florida Bay, including a comprehensive, coordinated ecosystem study with hydrodynamic modeling of Florida Bay and its connections to the Everglades, the Gulf of Mexico, and the Florida Keys Coral Reef ecosystem.

The WATER RESOURCES DEVELOPMENT ACT OF 1996, Public Law 104-303, Section 528, entitled “EVERGLADES AND SOUTH FLORIDA ECOSYSTEM RESTORATION” provided the Corps authority for the completion of a comprehensive restudy of the Central and Southern Florida Project. The pertinent portions of Section 528 provide as follows:

(a) DEFINITIONS.-In this section, the following definitions apply:

(1) CENTRAL AND SOUTHERN FLORIDA PROJECT.-The term "Central and Southern Florida Project" means the project for Central and Southern Florida authorized under the heading "CENTRAL AND SOUTHERN FLORIDA" in section 203 of the Flood Control Act of 1948 (62 Stat. 1176), and any modification to the project authorized by law.

(2) COMMISSION.-The term "Commission" means the Governor's Commission for a Sustainable South Florida, established by Executive Order of the Governor dated March 3, 1994.

(3) GOVERNOR.-The term "Governor" means the Governor of the State of Florida.

(4) SOUTH FLORIDA ECOSYSTEM.-The term "South Florida ecosystem" means the area consisting of the lands and waters within the boundary of the South Florida Water Management District, including the Everglades, the Florida Keys, and the contiguous near-shore coastal waters of South Florida.

(5) TASK FORCE.-The term "Task Force" means the South Florida Ecosystem Restoration Task Force established by subsection (f).

(b) RESTORATION ACTIVITIES.

(1) COMPREHENSIVE PLAN.

(A) DEVELOPMENT.--

(i) PURPOSE.-The Secretary shall develop, as expeditiously as practicable, a proposed comprehensive plan for the purpose of restoring, preserving, and protecting the South Florida ecosystem. The comprehensive plan shall provide for the protection of water quality in, and the reduction of the loss of fresh water from, the Everglades. The comprehensive plan shall include such features as are necessary to provide for the water-related needs of the region, including flood control, the enhancement of water supplies, and other objectives served by the Central and Southern Florida Project.

(ii) CONSIDERATIONS.-The comprehensive plan shall

(I) be developed by the Secretary in cooperation with the non-Federal project sponsor and in consultation with the Task Force; and

(II) consider the conceptual framework specified in the report entitled "Conceptual Plan for the Central and Southern Florida Project Restudy", published by the Commission and approved by the Governor.

(B) SUBMISSION.-Not later than July 1, 1999, the Secretary shall

(i) complete the feasibility phase of the Central and Southern Florida Project comprehensive review study as authorized by section 309(1) of the Water Resources Development Act of 1992 (106 Stat. 4844), and by 2 resolutions of the Committee on Public Works and Transportation of the House of Representatives, dated September 24, 1992; and

(ii) submit to Congress the plan developed under subparagraph (A)(i) consisting of a feasibility report and a programmatic environmental impact statement covering the proposed Federal action set forth in the plan.

(C) ADDITIONAL STUDIES AND ANALYSES.-Notwithstanding the completion of the feasibility report under subparagraph (B), the Secretary shall continue to conduct such studies and analyses as are necessary, consistent with subparagraph (A)(i).

(2) USE OF EXISTING AUTHORITY FOR UNCONSTRUCTED PROJECT FEATURES.-The Secretary shall design and construct any features of the Central and Southern Florida Project that are authorized on the date of the enactment of this Act or that may be implemented in accordance with the Secretary's authority to modify an authorized project, including features authorized under sections 315 and 316, with funds that are otherwise available, if the Secretary determines that the design and construction

(A) will accelerate the restoration, preservation, and protection of the South Florida ecosystem;

(B) will be generally consistent with the conceptual framework described in paragraph (1)(A)(ii)(II); and

(C) will be compatible with the overall authorized purposes of the Central and Southern Florida Project.

(3) CRITICAL RESTORATION PROJECTS.

(A) IN GENERAL.-In addition to the activities described in paragraphs (1) and (2), if the Secretary, in cooperation with the non-Federal project sponsor and the Task Force, determines that a restoration project for the South Florida ecosystem will produce independent, immediate, and substantial restoration, preservation, and protection benefits, and will be generally consistent with the conceptual framework described in paragraph (1)(A)(ii)(II), the Secretary shall proceed expeditiously with the implementation of the restoration project.

(B) INITIATION OF PROJECTS.-After September 30, 1999, no new projects may be initiated under subparagraph (A).

(C) AUTHORIZATION OF APPROPRIATIONS.

(i) IN GENERAL.-There is authorized to be appropriated to the Department of the Army to pay the Federal share of the cost of carrying out projects under subparagraph (A) $75,000,000 for the period consisting of fiscal years 1997 through 1999.

(ii) FEDERAL SHARE.-The Federal share of the cost of carrying out any 1 project under subparagraph (A) shall be not more than $25,000,000.

(4) GENERAL PROVISIONS.

(A) WATER QUALITY.-In carrying out activities described in this subsection and sections 315 and 316, the Secretary

(i) shall take into account the protection of water quality by considering applicable State water quality standards; and

(ii) may include in projects such features as are necessary to provide water to restore, preserve, and protect the South Florida ecosystem.

(B) COMPLIANCE WITH APPLICABLE LAW.-In carrying out the activities described in this subsection and subsection (c), the Secretary shall comply with any applicable Federal law, including the National Environmental Policy Act of 1969 (42 U.S.C. 4321 et seq.) and the Endangered Species Act of 1973 (16 U.S.C. 1531 et seq.).

(C) PUBLIC PARTICIPATION.-In developing the comprehensive plan under paragraph (1) and carrying out the activities described in this subsection and subsection (c), the Secretary shall provide for public review and comment on the activities in accordance with applicable Federal law.

(c) INTEGRATION OF OTHER ACTIVITIES.

(1) IN GENERAL.-In carrying out activities described in subsection (b), the Secretary shall integrate such activities with ongoing Federal and State projects and activities, including

(A) the project for the ecosystem restoration of the Kissimmee River, Florida, authorized by section 101 of the Water Resources Development Act of 1992 (106 Stat. 4802);

(B) the project for modifications to improve water deliveries into Everglades National Park authorized by section 104 of the Everglades National Park Protection and Expansion Act of 1989 (16 U.S.C. 410r-8);

(C) activities under the Florida Keys National Marine Sanctuary and Protection Act (16 U.S.C. 1433 note; 104 Stat. 3089); and

(D) the Everglades Construction Project of the State of Florida.

(2) STATUTORY CONSTRUCTION.

(A) EXISTING AUTHORITY.-Except as otherwise expressly provided in this section, nothing in this section affects any authority in effect on the date of the enactment of this Act, or any requirement of the authority, relating to participation in restoration activities in the South Florida ecosystem, including the projects and activities specified in paragraph (1), by

(i) the Department of the Interior;

(ii) the Department of Commerce;

(iii) the Department of the Army;

(iv) the Environmental Protection Agency;

(v) the Department of Agriculture;

(vi) the State of Florida; and

(vii) the South Florida Water Management District.

(B) NEW AUTHORITY.-Nothing in this section confers any new regulatory authority on any Federal or non-Federal entity that carries out any activity authorized by this section.

(d) JUSTIFICATION.

(1) IN GENERAL.-Notwithstanding section 209 of the Flood Control Act of 1970 (42 U.S.C. 1962-2) or any other provision of law, in carrying out the activities to restore, preserve, and protect the South Florida ecosystem described in subsection (b), the Secretary may determine that the activities

(A) are justified by the environmental benefits derived by the South Florida ecosystem in general and the Everglades and Florida Bay in particular; and

(B) shall not need further economic justification if the Secretary determines that the activities are cost-effective.

(2) APPLICABILITY.-Paragraph (1) shall not apply to any separable element intended to produce benefits that are predominantly unrelated to the restoration, preservation, and protection of the South Florida ecosystem.

(e) COST SHARING.

(1) IN GENERAL.-Except as provided in sections 315 and 316 and paragraph (2), the non-Federal share of the cost of activities described in subsection (b) shall be 50 percent.

(2) WATER QUALITY FEATURES.

(A) IN GENERAL.-Except as provided in subparagraph (B), the non-Federal share of the cost of project features to improve water quality described in subsection (b) shall be 100 percent.

(B) EXCEPTION.

(i) IN GENERAL.-Subject to clause (ii), if the Secretary determines that a project feature to improve water quality is essential to Everglades restoration, the non-Federal share of the cost of the feature shall be 50 percent.

(ii) APPLICABILITY.-Clause (i) shall not apply to any feature of the Everglades Construction Project of the State of Florida.

(3) OPERATION AND MAINTENANCE.-The operation and maintenance of projects carried out under this section shall be a non-Federal responsibility.

(4) CREDIT.-Regardless of the date of acquisition, the value of lands or interests in land acquired by non-Federal interests for any activity described in subsection (b) shall be included in the total cost of the activity and credited against the non-Federal share of the cost of the activity. Such value shall be determined by the Secretary.

(f) SOUTH FLORIDA ECOSYSTEM RESTORATION TASK FORCE.

(1) ESTABLISHMENT AND MEMBERSHIP.-There is established the South Florida Ecosystem Restoration Task Force, which shall consist of the

following members (or, in the case of a Federal agency, a designee at the level of assistant secretary or an equivalent level):

(A) The Secretary of the Interior, who shall serve as chairperson.

(B) The Secretary of Commerce.

(C) The Secretary.

(D) The Attorney General.

(E) The Administrator of the Environmental Protection Agency.

(F) The Secretary of Agriculture.

(G) The Secretary of Transportation.

(H) 1 representative of the Miccosukee Tribe of Indians of Florida, to be appointed by the Secretary of the Interior based on the recommendations of the tribal chairman.

(I) 1 representative of the Seminole Tribe of Florida, to be appointed by the Secretary of the Interior based on the recommendations of the tribal chairman.

(J) 2 representatives of the State of Florida, to be appointed by the Secretary of the Interior based on the recommendations of the Governor.

(K) 1 representative of the South Florida Water Management District, to be appointed by the Secretary of the Interior based on the recommendations of the Governor.

(L) 2 representatives of local government in the State of Florida, to be appointed by the Secretary of the Interior based on the recommendations of the Governor.

(2) DUTIES OF TASK FORCE.-The Task Force

(A) shall consult with, and provide recommendations to, the Secretary during development of the comprehensive plan under subsection (b)(1);

(B) shall coordinate the development of consistent policies, strategies, plans, programs, projects, activities, and priorities for addressing the restoration, preservation, and protection of the South Florida ecosystem;

(C) shall exchange information regarding programs, projects, and activities of the agencies and entities represented on the Task Force to promote ecosystem restoration and maintenance;

(D) shall establish a Florida-based working group which shall include representatives of the agencies and entities represented on the Task Force as well as other governmental entities as appropriate for the purpose of formulating, recommending, coordinating, and implementing the policies, strategies, plans, programs, projects, activities, and priorities of the Task Force;

(E) may, and the working group described in subparagraph (D), may

(i) establish such advisory bodies as are necessary to assist the Task Force in its duties, including public policy and scientific issues; and

(ii) select as an advisory body any entity, such as the Commission, that represents a broad variety of private and public interests;

(F) shall facilitate the resolution of interagency and intergovernmental conflicts associated with the restoration of the South Florida ecosystem among agencies and entities represented on the Task Force;

(G) shall coordinate scientific and other research associated with the restoration of the South Florida ecosystem;

(H) shall provide assistance and support to agencies and entities represented on the Task Force in their restoration activities;

(I) shall prepare an integrated financial plan and recommendations for coordinated budget requests for the funds proposed to be expended by agencies and entities represented on the Task Force for the restoration, preservation, and protection of the South Florida ecosystem; and

(J) shall submit a biennial report to Congress that summarizes

(i) the activities of the Task Force;

(ii) the policies, strategies, plans, programs, projects, activities, and priorities planned, developed, or implemented for the restoration of the South Florida ecosystem; and

(iii) progress made toward the restoration.

(3) PROCEDURES AND ADVICE.

(A) PUBLIC PARTICIPATION.

(i) IN GENERAL.-The Task Force shall implement procedures to facilitate public participation in the advisory process, including providing advance notice of meetings, providing adequate opportunity for public input and comment, maintaining appropriate records, and making a record of the proceedings of meetings available for public inspection.

(ii) OVERSIGHT.-The Secretary of the Interior shall ensure that the procedures described in clause (i) are adopted and implemented and that the records described in clause (i) are accurately maintained and available for public inspection.

(B) ADVISORS TO THE TASK FORCE AND WORKING GROUP.-The Task Force or the working group described in paragraph (2)(D) may seek advice and input from any interested, knowledgeable, or affected party as the Task Force or working group, respectively, determines necessary to perform the duties described in paragraph (2).

(C) APPLICATION OF THE FEDERAL ADVISORY COMMITTEE ACT.

(i) TASK FORCE AND WORKING GROUP.-The Task Force and the working group shall not be considered advisory committees under the Federal Advisory Committee Act (5 U.S.C.App.).

(ii) ADVISORS.-Seeking advice and input under subparagraph (B) shall not be subject to the Federal Advisory Committee Act (5 U.S.C.App.).

(4) COMPENSATION.-A member of the Task Force shall receive no compensation for the service of the member on the Task Force.

(5) TRAVEL EXPENSES.-Travel expenses incurred by a member of the Task Force in the performance of services for the Task Force shall be paid by the agency, tribe, or government that the member represents.

F.3 OTHER AUTHORITIES

FEDERAL AGRICULTURE IMPROVEMENT AND REFORM ACT OF 1996, Public Law 104-127, SECTION 390. “EVERGLADES ECOSYSTEM RESTORATION”, subsections (a), (b). (c), (d) and (e) [hereinafter referred to as the Farm Bill]:

(a) IN GENERAL.-On July 1, 1996, out of any funds in the Treasury not otherwise appropriated, the Secretary of the Treasury shall provide $200,000,000 to the Secretary of the Interior to carry out this section.

(b) ENTITLEMENT.-The Secretary of the Interior (referred to in this section as the "Secretary")

(1) shall be entitled to receive the funds made available under subsection (a);

(2) shall accept the funds; and

(3) shall use the funds to

(A) conduct restoration activities in the Everglades ecosystem in South Florida, which shall include the acquisition of real property and interests in real property located within the Everglades ecosystem; and

(B) fund resource protection and resource maintenance activities in the Everglades ecosystem.

(c) SAVINGS PROVISION.-Nothing in this subsection precludes the Secretary from transferring funds to the Army Corps of Engineers, the State of Florida, or the South Florida Water Management District to carry out subsection (b)(3).

(d) DEADLINE.-The Secretary shall use the funds made available under subsection (a) for restoration activities referred to in subsection (b)(3) not later than December 31, 1999.

(e) REPORT TO CONGRESS.-For each of calendar years 1996 through 1999, the Secretary shall submit an annual report to Congress describing all activities carried out under subsection (b)(3).

F.4 STUDY AREA

The study area, as shown in Figure 1-2 in the feasibility report, includes all of the area of the C&SF Project with the exception of the Upper St. Johns River Basin.

The study area stretches from Orlando to the southern tip of Florida and encompasses all or parts of 16 counties, an area of approximately 18,000 square miles. Major areas of the project include the Kissimmee River, Lake Okeechobee, Everglades Agricultural Area, Water Conservation Areas, Lower East Coast, Everglades National Park, Big Cypress National Preserve, and Florida Bay.

F.5 REAL ESTATE LEVEL OF DETAIL FOR THIS STUDY

The purpose of the feasibility phase of the Comprehensive Review Study is to review the entire C&SF Project, with the exception of the Upper St. Johns River Basin, to restore the Everglades and Florida Bay ecosystems while still providing for other water-related needs. Due to the magnitude of the study area, the level of detail provided by the other technical elements involved in this phase of the study is at a lower level than normally provided for a typical feasibility study. On December 5-6, 1996, a Special Review Conference was held in Jacksonville, Florida, to address various issues that would affect the development of the Comprehensive Plan. It also served to develop guidance to implement and complete the Comprehensive Plan for submittal to Congress. Enclosed, as Exhibit A, is the CECW-PE Memorandum Subject: C&SF Project Comprehensive Review Study Special Review Conference Project Guidance Memorandum that documents the issues, discussions and decisions that arose from this conference.

Some of the points of the Project Guidance Memorandum regard to the level of detail for this phase of the study are:

> *Due to the need to complete a Comprehensive Plan report in a timely manner and the geographic extent of the study area, the level of analysis and engineering detail will be less than traditionally provided to support plan selection and a base line cost estimate for projects recommended for Congressional authorization. Real estate cost estimates will be based on the analysis and assumptions made during the process of formulating and developing the components of the Comprehensive plan. A real estate baseline cost estimate will be between what is normally contained in a Reconnaissance Report and what is normally contained in a Feasibility Study, and will be provided as a range of values for each component. A gross appraisal will not be completed for the Comprehensive Plan, but appropriate documents will be prepared for each subsequent design document.*

F.6 COST ESTIMATE INFORMATION

Jacksonville District, Real Estate Division was tasked with developing real estate property cost estimates based on various categories of land, to be applied to each component, accordingly.

Land cost estimates were developed based on various categories of land within each county, which were applied to each component, accordingly. The land cost estimates were based on sales data obtained by the Jacksonville District, information from County Property Appraisers/Assessors, county tract appraisal information, the Jacksonville District staff appraiser's general county wide knowledge, input from the South Florida Water Management District, and actual land acquisition costs of lands already acquired by the South Florida Water Management District. For the purpose of this study, fee value was assumed in estimating all land costs to arrive at the per acre value. The actual required estates will be determined in each subsequent design document. Given the massive size of the study area, the broad conceptual nature and number of components, the level of detail for this phase of the study did not include: the determination of numbers, types and locations of structures or improvements; actual number of tracts; the associated relocations assistance costs (except for component VV, in which that information was available); or the possible severance damages associated with each plan component. The cost estimates for each of the components are preliminary, more detail will be presented for the appropriate design document for each component. According to the Study Team, the proposed acquisition lines for each of the components will primarily circumvent existing improvements, leaving only a minimum number of affected structures to be acquired. For this study, the contingency factor for each component was adjusted upward to cover unknown severance damages, number of tracts to be acquired, improvement costs, condemnations, and relocations assistance payments. A reliable determination of affected improvements and possible severance damages will be accomplished in each subsequent design document

F.6.1 ACQUISITION/ADMINISTRATIVE COST ESTIMATES

Acquisition/administrative estimates for the non-Federal sponsor include costs that will be incurred during real estate acquisition, such as the costs for acquisitions, appraisals, title insurance, surveys, closings, condemnations, relocation assistance, temporary permits, and damage claims. The Federal acquisition/administrative estimates include costs for project planning, obtaining temporary permits, review of acquisitions by the non-Federal sponsor, review of appraisals obtained by the non-Federal sponsor, review of Public Law 91-646 assistance costs, review of condemnations performed by the non-Federal sponsor, and monitoring of the acquisition process. Historical acquisition/administrative cost estimate data was relied upon in determining the proposed acquisition/administrative costs for each of the alternative plans addressed in this report. The approximate number of affected ownership tracts was estimated using Experian-computer ownership data from some Florida counties and plat books for the counties in which Experian data was not available.

In calculating the acquisition/administrative cost estimates for almost all of the components, an amount of $12,000 was applied to each affected tract for proposed non-Federal acquisition/administrative sponsor costs. An amount of $6,000 was estimated for each tract for proposed Federal acquisition/administrative costs. In certain components, both the Federal and non-Federal acquisition/administrative costs were reduced if there were an extremely large number of tracts in the component or increased because there was a lack of information regarding the estimated number of tracts.

Table F-1 entitled Federal and non-Federal Administrative/Acquisition Costs shows the probable administrative/acquisition costs for each component in the recommended Comprehensive Plan – Alternative D13R together with the Other Project Elements.

F.6.2 PUBLIC LAW 91-646 COST ESTIMATES

Due to the limited information available and the magnitude of the study area, it was assumed that the proposed acquisition lines for each component would affect only a minimum amount of structures. For each of the components (except Component VV, in which some improvement information was obtained), unknown improvement costs and relocations assistance estimates are covered in a higher than usual contingency cost added in for each component.

F.6.3 REAL ESTATE CONTINGENCY COST ESTIMATES

Typically, a real estate contingency factor of 25 percent is added in to the total real estate project cost, to cover uncertainties associated with elements such as valuation variance, negotiation latitude, condemnation awards and interest, and refinement of boundary lines during ownership verification. For this study, in most components, a contingency factor from 5 percent to 50 percent (depending on the reliability of the estimated cost information) has been applied to each of the components. ***Table F-2*** shows the contingency factor applied to each component in the Recommended Comprehensive Plan – Alternative D13R together with the Other Project Elements.

F.7 PRELIMINARY AND ALTERNATIVE PLANS

Five preliminary alternatives (Preliminary Alternatives 1 through 5), involving a combination of components, were originally studied. Preliminary cost estimates were generated for the purpose of comparing these preliminary alternative plans, and are based on conceptual designs. After the preliminary alternative screening, a total of four revised alternatives (Alternatives A through D) were determined for further study. Only the components in Alternatives A through D that include real estate requirements are addressed in this section of the Real Estate Appendix.

There were a total of 44 components requiring real estate cost estimates for Alternatives A through D. Following are descriptions and corresponding real estate costs for all of the components making up Alternatives A through D. The alternatives to which a particular component pertains are shown next to each heading. Many components remain constant throughout the Alternatives, as are shown below. Only the components that include real estate requirements are addressed in this appendix. ***Table F-3*** provides a comparison of Alternatives A through D as well as a comparison to the Initial Draft Plan - Alternative D13R, including the estimated low-end costs, the estimated high-end costs, and the estimated probable costs for Alternative D13R. For more detailed descriptions of the components in Alternatives A through D, refer to Appendix A.

Component A6 (Alternatives A, B, C &D)

The North of Lake Okeechobee Storage component consists of constructing a storage reservoir (20,000 acres at 10 feet maximum depth) north of Lake Okeechobee. The purpose would be to incorporate climate-based inflow forecasting to increase the utilization of the reservoir to provide additional flood protection, water supply and environmental enhancement. The reservoir could be located in any of five counties (Glades, Highlands, Okeechobee, Osceola, and Polk). The location of the reservoir would be on land currently agricultural in nature and as such, the appraiser valued land within the five counties that is currently of general agriculture use (pasture and citrus). The total estimated real estate cost of this component is $189,720,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component B2 (Alternatives A, B, C & D)

The Storage Reservoir St. Lucie/C-44 Basin component consists of establishing a storage reservoir (10,000 acres at 4 feet maximum depth) in the St. Lucie Basin. The purpose would be to capture local runoff from C-44 for flood attenuation, water supply benefits including environmental water supply deliveries to the estuary, and water quality benefits to reduce salinity and nutrient impacts of runoff to the estuary. The general area designated for this reservoir is north of the St. Lucie Waterway and in an easterly direction of Indiantown in Okeechobee County. This area appears to be primarily in citrus groves, with the total estimated real estate cost of this component being $90,675,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component D5 (Alternatives A, B, C & D)

Storage Reservoir with Aquifer Storage and Recovery (44, 5 million gallons per day wells) Caloosahatchee/C-43 Basin. This component's purpose would be to capture basin runoff and regulatory releases from Lake Okeechobee to provide water supply benefits (20,000 acres at 8 feet maximum depth), some flood attenuation and environmental water supply deliveries to the Caloosahatchee Estuary. This component would be operated in conjunction with the DDD5 component. The 20,000-acre storage site would be located in Glades County, on presumably agricultural land. The total estimated real estate cost of this component is $75,621,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component G3 (Alternatives A and B) and Component G5 (Alternatives C, & D)

Palm Beach Everglades Agricultural Area Storage Reservoir. For real estate purposes, both components G3 (Alternatives A and B) and G5 (Alternatives C and D) have identical real estate requirements of 60,000 acres, however, the components differ in the division of the 60,000 acres into compartments. Component G3 consists of one 20,000-acre compartment at 6 feet maximum depth for supplying Everglades Agricultural Area irrigation demands and one 40,000-acre compartment at 6 feet maximum depth for supplying environmental demands in the Everglades Agricultural Area with increased conveyance from Lake Okeechobee to the reservoir. Component G5 consists of three 20,000-acre compartments all at 6 feet maximum depth. The purpose, of both Components G3 and G5, are: (1) to improve timing of environmental deliveries to the Water Conservation Areas, including reducing damaging flood releases from the Everglades Agricultural Areas to the Water Conservation Areas; (2) to reduce Lake Okeechobee regulatory releases to estuaries; to meet supplemental agricultural irrigation demands; and (3) to increase flood protection within the Everglades Agricultural Area. The conveyance capacity of the Miami and North New River Canals between Lake Okeechobee and the storage reservoirs would be increased to convey additional Lake Okeechobee regulatory releases that would have otherwise been discharged to the Caloosahatchee and St. Lucie Estuaries. The proposed area for the 60,000-acre storage site is not clearly delineated, but lies south of Lake Okeechobee, between the North New River and the Miami Canals. This area is primarily sugar cane and was valued as such. The total estimated real estate cost of either of Components G3 and G5 is $285,852,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component K2 (Alternative A), Component K4 (Alternatives B & C) and Component K6 (Alternative D)

Water Preserve Areas / L-8 Project Phase II. For preliminary real estate cost estimating purposes, Components K2, K4 and K6 had identical real estate requirements. All three components consist of capturing water and improving stages in the West Palm Beach Water Catchment Area to reduce water supply restrictions in the Northern Palm Beach County Service Area. The intent is to increase water supply availability and provide pass through flow to enhance hydroperiods in Loxahatchee Slough and increase base flows to the Northwest Fork of the Loxahatchee River. The land required for this component is approximately 40 acres, and is valued as pasture/open land. The total estimated real estate cost of any of the three Components (K2, K4, or K6) is $2,576,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component M4 (Alternatives A, B & C)

Site 1 Impoundment- Palm Beach County component consists of a 1,660-acre impoundment site to include aquifer storage and recovery wells in Palm Beach County. The purpose of this component is to increase regional water resources and supplement water deliveries to the Hillsboro Canal during the dry-season. Existing land owned by South Florida Water Management District is proposed for the impoundment site. The total estimated real estate cost of this component is $8,734,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component M6 (Alternative D)

Site 1 Impoundment – Palm Beach County component consists of the same 1,660 acre impoundment site as in Component M4 owned by the South Florida Water Management District, plus an additional 800 acres (land-type unknown) located south of the 1,660-acre site, and also incorporates a portion of the Hillsboro Canal into the reservoir to increase the aquifer storage recovery capacity. The purpose is to increase regional water resources and supplement water deliveries to the Hillsboro Canal during the dry-season. The total estimated real estate cost of this component is $22,779,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component O1 (Alternative A), Component O4 (Alternatives A, B &C)

The Water Conservation Area 3A and 3B Levee Seepage Management in Broward County. For real estate purposes, both of these components (O1 and O4) have identical real estate requirements. The purpose is to reduce seepage from Water Conservation Areas 3A and 3B, to improve hydropatterns within the Water Conservation Areas by utilizing the marsh areas that are located east of the Water Conservation Areas and west of U.S. Highway 27, and to allow higher water levels and longer inundation durations within those marshes. Seepage from the marshes will be collected and returned to the Water Conservation Areas to maintain flood protection. Either of these components would also serve to separate Water Conservation Area 3A seepage water from urban runoff originating in the C-11 Basin. The real estate involved is land required for the location of a divide structure being added to the C-11 Canal just east of US 27, and a new levee west of US 27. The amount of acreage needed for either of these components is estimated at 6,542 acres of primarily vacant prairie land. The total estimated real estate cost for either of the components (O1 or O4) is $47,601,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component P2 (Alternative A)

The North New River Diversion Canal and Treatment Facility component consists of a diversion canal and treatment facility in Broward County with increased pump and structure capacities and seasonal S-141 operations. The purpose of this component is to capture excess North New River Canal and Water Conservation Area 2B water, store and treat it in western C-11, and backpump it to Water Conservation Area 3A. This will (1) restore a portion of water deliveries to Water Conservation Area 3A that are eliminated by segregating the C-11 runoff from levee seepage, (2) reduce stages above the Natural Systems Model in Water Conservation 2B, and (3) divert water through Water Conservation Areas 3A and 3B to Northeast Shark River Slough. Untreated, western C-11 runoff that is presently backpumped through the S-9 pump station into Water Conservation Area 3A will be redirected into the new canal and diverted to the Central Lake Belt Storage Area (refer to Component Q1). The water quality treatment area will consist of about 1,600 acres, in an area not specifically identified within Broward County. The diversion canal consists of about 400 acres, also type unknown. The total estimated real estate cost of this component is $68,167,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/ acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component Q1 (Alternative A)

Western C-11 Diversion Canal (to Central Lake Belt Storage) component is located in Broward County and its purpose is to divert untreated runoff from western C-11 (presently discharged into Water Conservation Area 3A) and excess flows from the North New River and C-9 Canals to the Central Lake Belt Reservoir. Approximately 535 acres of seemingly agricultural land will be needed for this component. The total estimated real estate cost is $5,156,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/ acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component Q4 (Alternative B) and Component Q5 (Alternatives C & D)

Western C-11 Diversion Impoundment and Canal (1,600 acres of stormwater treatment area/impoundment and 2,500 cfs diversion canal-935 acres). The purpose of both of these components (Q4 and Q5) is to divert untreated runoff from western C-11 that is presently discharged into Water Conservation Area 3A through the C-11 Stormwater Treatment Area/Impoundment and then into the North Lake Belt Storage Area. For real estate purposes, the real estate requirements of both of these components (Q4 and Q5) are identical and consist of a 1,600-acre impoundment area and 935 acres of canal, on what appears to be agricultural land. The total estimated cost of either of these components (Q4 or Q5) is $73,323,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component R3 (Alternative A) and Component R4 (Alternatives B, C & D)

C-9 Stormwater Treatment Area/Impoundment (2,500 acres at 4 feet maximum depth). The purpose of components R3 and R4 is to provide treatment of water supply deliveries from the North Lake Belt Storage Area prior to deliveries to the C-9, C-6/C-7 and C-2/C-4 Canals, and to provide groundwater recharge within the basin and seepage control of Water Conservation Area 3 and buffer areas to the west. For real estate purposes, the real estate requirements are identical for both components R3 and R4 and consist of the 2,500 impoundment area (land type unknown) within Broward County. The total estimated real estate cost for the components (R3 or R4) is $71,024,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component S3 (Alternative A)

Central Lake Belt In-ground Storage Area. The purpose of this component is to capture a portion of runoff from western North New River, C-11, C-9, C-6 and C-7 Basins in an in-ground reservoir, which will allow storage of untreated runoff without concerns of ground water contamination. The stored water will be used to maintain stages during the dry season in the C-9, C-6, Northwest Wellfield protection canal, C-4, C-2 and the South Miami-Dade Conveyance System Canals. The component will require approximately 6,070 acres of land identified as wetland prairie, melaleuca trees and rock quarry lands, located within Miami-Dade County. The total estimated real estate cost of this component is $188,007,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component S5 (Alternatives B and C) and Component S6 (Alternative D)

Central Lake Belt Storage Area (CLBSA) – The purpose of either of these components (S5 or S6) is to receive and store excess water from Water Conservation Area 2B, 3A and 3B without groundwater seepage losses in this highly transmissive region. The stored water will be provided based on priority to 1) Northeast Shark River Slough, 2) Water Conservation Area 3B, 3) to supply flows to Biscayne Bay and 4) when available to meet Snapper Creek demands and to maintain Dade-Broward levee borrow canal at elevation 5.0 feet NGVD. For real estate purposes, the land required for the components (S5 or S6) is identical and consists of approximately 5,770 acres of vacant and quarry lands within Miami-Dade County. The total estimated real estate cost of either of these components (S5 or S6) is $84,507,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component T6 (Alternatives A, B, C & D)

C-4 Structures (2). The purpose of this component is to maintain higher water levels in the C-4 Canal; to reduce seepage losses from the Pennsuco Wetlands and areas west of the Dade-Broward Levee; and to reduce deliveries from Lake Okeechobee and the Water Conservation Areas by diverting dry season stormwater flows into the C-2 Canal to increase recharge to several nearby coastal wellfields. Alternative D includes the second C-4 structure. Approximately 2 acres of commercial land in Miami-Dade County were valued for this component. The total estimated real estate cost of this component is $446,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/ acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component U3 (Alternative A), Component U4 (Alternatives B and C) and Component U6 (Alternative D)

Bird Drive Recharge Area (2,877 acres at 4 feet maximum depth). The purpose of each of these components U3, U4 and U6 is to provide flood peak attenuation by capturing runoff from western C-4 Basin and pumping it to the Bird Drive Recharge Area, and to enhance groundwater recharge and reduce seepage from the Everglades National Park buffer areas by increasing water table elevations east of Krome Avenue, with the introduction of inflows from the West Dade Wastewater Treatment Plant (treatment plant only in U6). The facility will also provide water supply deliveries to the South Dade Conveyance System and Northeast Shark River Slough. For real estate purposes, the land requirements are the same for all three of the components (U3, U4 or U6) and consist of 2,877 acres of mostly wetlands within Miami-Dade County. The total estimated real estate cost of either of the three components (U3, U4 or U6) is $71,625,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component V2 (Alternative A)

L-31N Levee Improvements for Seepage Management. The purpose of this component is to manage levee seepage along the eastern edge (L-31N) of Everglades National Park to eliminate losses to the East Coast. An additional feature was added to reduce all wet-season seepage/ground water flows to the east to help restore hydropatterns in Everglades National Park. The real estate requirements consist of 40 acres of land (type unknown) within Miami-Dade County. The total estimated cost of this component is $2,576,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component W2 (Alternatives A, B, C & D)

Taylor Creek/Nubbin Slough Storage and Treatment Area. The purpose of this component is to provide flood protection, water quality treatment, estuary protection and water supply benefits. Local runoff from the Taylor Creek/Nubbin Slough Basins would be pumped into a 5,000 acre reservoir and then into a 5,000-acre stormwater treatment area. The real estate requirements consist of two 5,000-acre sites of primarily pastureland within Okeechobee and/or St. Lucie Counties. The total estimated real estate cost of this component is $29,700,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component X6 (Alternatives A, B, C & D)

C-17 Backpumping. The purpose of this component is to reduce water supply restrictions in Northern Palm Beach County service area by providing additional flows from the C-17 Basin to the West Palm Beach Water Catchment Area and enhancing hydroperiods in the Loxahatchee Slough. A 550-acre site (land with mostly standing water) located within Palm Beach County is required for this component. The total estimated real estate cost of this component is $10,367,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component Y6 (Alternatives A, B, C & D)

C-51 Backpumping to Water Catchment Area. The purpose of this component is to increase regional water resources, to reduce water supply restrictions in Northern Palm Beach County Service Area by providing additional flows from the C-51 West Basin (which would otherwise be sent to tide) to the West Palm Beach Water Catchment Area, and to enhance hydroperiods in Loxahatchee Slough. Approximately 710 acres of land (primarily with standing water) located in Palm Beach County is required for this component. The total estimated real estate cost of this component is $13,475,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component BB4 (Alternatives A and B) and Component BB5 (Alternatives C & D)

Dade-Broward Levee/Pennsuco Wetlands. The purpose of this component is to reduce seepage to the east from the Pennsuco Wetlands and southern Water Conservation Area 3B, enhance hydroperiods in the Pennsuco Wetlands, and enhance recharge to Miami-Dade County's Northwest Wellfield. Approximately 70 acres of open pastureland in Miami-Dade County were valued for either component BB4 and BB5. The total real estate cost estimate of either component BB4 or BB5 is $4,361,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component FF3 (Alternative A)

Construction of S-356 A & B Structures (L-31N along east side of Northeast Shark River Slough). The purpose of this component is to improve deliveries to Northeast Shark River Slough in Everglades National Park and reduce seepage to Lower East Coast Service Area 3. Approximately 4.0 acres of pastureland located in

Miami-Dade County was valued for this component. The total estimated real estate cost of this component is $300,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component FF4 (Alternatives B, C & D)

Construction of S-356 A & B Structures and relocation of a portion of L-31N: The purpose of this component is to improve deliveries to Northeast Shark River Slough in Everglades National Park and reduce seepage to Lower East Coast Service Area 3. Approximately 3,947 acres of farmland with some quarry land located in Miami-Dade County is required for this component. The total estimated real estate cost of this component is $60,819,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component GG4 (Alternatives A, B, C & D)

Lake Okeechobee Aquifer Storage and Recovery. The purpose of this component is to utilize climate based operational rules for the aquifer storage and recovery wells, to provide additional regional storage while reducing both evapotranspiration losses and the amount of land removed from current land use (e.g. agriculture) that would normally be associated with construction and operation of above-ground storage facilities (reservoirs); to increase the Lake's water storage capability to better meet regional water supply demands for agriculture, Lower East Coast urban areas, and the Everglades; to manage a portion of regulatory releases from the Lake primarily to improve Everglades hydropatterns, to meet environmental targets within the Water Conservation Areas and to meet supplemental water supply demands of the Lower East Coast; to reduce harmful regulatory discharges to the St. Lucie and Caloosahatchee Estuaries; and to maintain existing level of flood protection. This component would be located within Glades and/or Okeechobee Counties and would consist of the acquisition of approximately 300 acres of open pastureland. The total estimated real estate cost of this component is $7,065,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component KK4 (Alternatives A, B, C & D)

Loxahatchee National Wildlife Refuge Internal Canal Structures. The purpose of this component is to improve timing and location of water depths in the Refuge by keeping the borrow canal structures closed except to pass Stormwater Treatment Areas 1 East and 1 West outflow and water supply deliveries. The real estate requirements consist of the acquisition of approximately 5.0 acres of open pastureland within Palm Beach County. The total real estate cost of this component is $345,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component LL3 (Alternative A) and Component LL6 (Alternative D)

C-51 Regional Groundwater Aquifer Storage and Recovery (34 well clusters). Either of these components would be located in Palm Beach County. The purpose would be to capture and store excess water during wet periods, then recover the water for utilization during dry periods to increase regional water resources. For real estate purposes, both of these components (LL3 and LL6) have identical real estate requirements. Approximately 34 acres of open pastureland with some commercial land was valued for this component. The total estimated real estate cost of this component is $7,395,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component LL4 (Alternatives B & C)

C-51 Regional Groundwater Aquifer Storage and Recovery (54 well clusters). This component would be located in Palm Beach County. Its purpose would be to increase regional water resources by capturing and storing excess water during wet periods and recover the water for utilization during dry periods. Approximately 54 acres of open pastureland with some commercial land was valued for this component. The total estimated real estate cost of this component is $11,745,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component MM4 (Alternatives A, B & C)

Hillsboro Canal Basin Regional Groundwater Aquifer Storage and Recovery (22 well clusters): The purpose of this component is to increase regional water resources by capturing and storing excess water during wet periods and recover the water for utilization during dry periods. This component would be located in Palm Beach and/or Broward Counties and would require approximately 22 acres of land. Commercial land was valued for this component, the total estimated real estate cost is $4,455,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component PP3 (Alternative A)

Backpumping of the C-7 Basin to the Central Lake Belt In-ground Storage Reservoir via the C-6 Canal: The purpose of this component is to backpump a portion of excess runoff from the C-7 Basin, previously lost to tide, to the Central Lake Belt Storage Reservoir to be used for water supply, and to decrease flooding problems in the C-7 Basin. Approximately 4.0 acres of commercial land in Miami-Dade County was valued for this component. The total estimated real estate cost of this component is $1,064,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component SS4 (Alternatives B, C & D)

Reroute Miami-Dade County Water Supply Deliveries. The purpose of this component is to reroute water supply deliveries made to Miami-Dade County from the Miami and Tamiami Canals and Water Conservation Area 3 to the North New River Canal due to the backfilling of the Miami Canal as part of the decompartmentalization of Water Conservation Area 3. Approximately 200 acres of land to be located within Palm Beach, Broward and Miami-Dade Counties would be required for this component (residential-type land was valued). The total estimated real estate cost of this component is $18,480,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component UU6 (Alternatives A, B, C & D)

Storage Reservoirs (20,200 acres at 8 feet maximum depth and 15,000 acres at 2 feet maximum depth). The purpose of this component is to capture local runoff from the C-23, C-24, and Northfork and Southfork Basins of the St. Lucie River Estuary for: flood flow attenuation to the estuary, water supply benefits including environmental water supply deliveries to the estuary, and water quality benefits to reduce salinity and nutrient impacts of runoff to the estuary. Approximately 35,200 acres of land within Martin and St. Lucie Counties were valued for this component. The total estimated real estate value of this component is $244,578,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component VV4 (Alternative B), Component VV5 (Alternative C), and Component VV6 (Alternative D)

Palm Beach County Agricultural Reserve Reservoir. For real estate purposes, the real estate requirements for the three components (VV4, VV5 and VV6) are identical. In general, the purpose of any of these components is to increase regional water resources in central and southern Palm Beach County by capturing and storing water currently discharged to tide to be used to maintain canal stages during the dry season. Approximately 1,660 acres of agricultural land in Palm Beach County is required for any of the three components (VV4, VV5 or VV6). The total estimated real estate cost of any of the three components (VV4, VV5 or VV6) is $57,657,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. An estimated 18 improvements would be acquired at a cost of $4,500,000 with relocation assistance costs of $414,000 included.

Component WW4 (Alternative B)

C-111N Spreader Canal. The purpose of this component is to reduce wet season flows in C-111, improve deliveries to Model Lands and Southern Glades and decrease potential flood risk in the lower south Miami-Dade area. Approximately 9,225 acres of vacant land in Miami-Dade County will be required for this component. The total estimated real estate cost is $24,513,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component WW5 (Alternatives C & D)

C-111N Spreader Canal. The purpose of this component is to reduce wet season flows in C-111, improve deliveries to Model Lands and Southern Glades and decrease potential flood risk in the lower south Miami-Dade area. C-111N was extended east of Card Sound Road. Approximately 12,415 acres of vacant land in Miami-Dade County was valued for this component. The total estimated real estate cost of this component is $45,741,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component XX4 (Alternative B)

North Lake Belt Storage Area. The purpose of this component is to increase regional water resources by capturing a portion of runoff from western C-6, western C-11 and C-9 Basins without seepage losses in this very transmissive groundwater region and without concerns of ground water contamination from untreated runoff. The stored water will be used to maintain stages during the dry season in the C-9, C-6, C-7, C-4 and C-2 Canals. Approximately 5,861 acres of vacant and quarry land in Miami-Dade County was valued for this component. The total estimated real estate cost of this component is $130,743,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component XX5 (Alternative C) and Component XX6 (Alternative D)

North Lake Belt Storage Area. The purpose of both of these components (XX5 and XX6) is to increase regional water resources by capturing a portion of runoff from western C-6, western C-11 and C-9 Basins without seepage losses in this very transmissive groundwater region and without concerns of ground water contamination from untreated runoff. The stored water will be used to maintain stages during the dry season in the C-9, C-6, C-7, C-4 and C-2 Canals. The real estate requirement for either Components XX5 or XX6 are the same. Approximately 5,861 acres of vacant and quarry land in Miami-Dade County was valued for this component. The total estimated real estate cost of both Component XX5 or XX6 is $121,302,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component YY4 (Alternatives B, C & D)

Divert Water Conservation Area 2 flows to Northeast Shark River Slough or Central Lake Belt Storage in Broward County. The purpose of this component is to capture excess water in Water Conservation Area 2B, to reduce stages above targets, and to divert water through improved L-37 and L-33 borrow canals to meet the following prioritized demands: (1) Northeast Shark River Slough; or (2) Central Lake Belt Area for future delivery to Northeast Shark River Slough; (3) to Snapper Creek; and (4) to maintain Miami-Dade-Broward levee borrow canal at elevation 5.0 feet NGVD. Approximately 835 acres of land (type unknown) in Miami-Dade County would be required for this component. The total estimated real estate cost of this component is $12,145,000, which includes the estimated lands and damages costs, Federal and non-Federal administrative/acquisition costs, and a contingency. No improvements or relocation assistance costs were included.

Component ZZ5 (Alternatives C & D)
